Hernias present with groin bulges that may extend into the scrotum or labia. When fluid alone is present in a persistent processus vaginalis, it is known as a hydrocele. Hydroceles may be simple collections present at birth in the normally present pouch around the testis, or they may develop after birth along any portion of the path of the processus vaginalis. Hydroceles present at birth may spontaneously resolve, although it may take up to a year. Hydroceles that develop after birth presumably have an open connection into the abdomen and are unlikely to resolve, so they are treated as inguinal hernias, although their repair is not urgent. Larger hydroceles can be difficult to differentiate from inguinal hernias, especially when hydrocele fluid extends up into the inguinal canal.

Neonatal Gastroesophageal Reflux

MORGAN K. RICHARDS AND ADAM B. GOLDIN

KEY POINTS

- Gastroesophageal reflux is physiologic in newborns, but when associated with complications it is classified as gastroesophageal reflux disease (GERD) and may warrant intervention.
- The symptoms of gastroesophageal reflux disease overlap with many other common conditions.
- Pathophysiologic symptoms in infants often attributed to GERD may be divided into three categories: benign esophageal, serious esophageal, and extraesophageal.
- There is no gold standard test for the diagnosis of GERD in infants; thus the choice of intervention and measure of its success must be guided by the presenting complaints.
- No histamine antagonists or proton pump inhibitors have US Food and Drug Administration approval for use in infants.
- There is significant geographic and institutional variation in the frequency and type of antireflux operative intervention.

Background

Gastroesophageal reflux (GER) is the physiologic passage of gastric contents into the esophagus. It is a naturally occurring phenomenon in infants, children, and adults that typically lasts fewer than 3 minutes, has minimal or no associated symptoms, and usually occurs in the postprandial period. It may occur several times per day and on occasion may be associated with spit-ups or vomiting. Normal physiologic GER in infants is common, occurring in as many as 65% of infants younger than 4 months, naturally decreasing in frequency over time, affecting only 1% by 12 months (Henry, 2004). The trajectory of this natural history is likely related to lengthening of the esophagus and a decrease in episodes of transient relaxation of the lower esophageal sphincter (Henry, 2004).

Normal Anatomy and Physiology

The normal swallowing mechanism consists of a food or saliva bolus traveling from the mouth to the pharynx through the esophagus to the stomach and is propelled forward with peristaltic muscle contractions of the esophagus. The lower esophageal sphincter, located at the gastroesophageal junction, has a resting tone that increases with increasing gastric distention, which acts as an anatomic barrier for refluxing gastric contents into the esophageal lumen. Decreased lower esophageal sphincter pressure occurs with swallowing and release of gas from the stomach in the form of eructation (Henry, 2004).

Abnormal Physiology: Gastroesophageal Reflux Disease

In contrast, gastroesophageal reflux disease (GERD) is the pathophysiologic passage of gastric material into the esophagus that is associated with a variety of significant symptoms and/or complications (Milla et al., 2002; Gold, 2004; Hassall, 2005; Vandenplas et al., 2009). GERD is uncommon in infants, affecting only 1 in 300, though certain populations such as premature or critically ill infants are believed to be at greater risk (Henry, 2004).

The complexity in distinguishing GER from GERD, however, lies in defining significant symptoms and complications and clearly proving that they are directly caused by the passage of gastric content into the esophagus. Several symptoms in infants such as frequent vomiting, irritability, distress, and unexplained crying are common. While these symptoms can be attributed to GER and GERD, they can also be due to many other underlying problems such as cow's milk protein allergy, neurologic disorders, urinary tract infection, and constipation (Vandenplas et al., 2009). In general, symptoms that are not causing physiologic or behavioral impact may need no additional evaluation. For example, the "happy spitter" is an infant who regurgitates a small amount after a few feeds each day but continues to grow and gain weight along a normal trajectory. When recurrent emesis is coupled with poor weight gain, however, a complete work-up for GERD and other diagnoses in the differential should be considered (Hassall 2005; Vandenplas et al., 2009).

Pathophysiologic symptoms in infants that are often attributed to GERD may be divided into three categories: benign esophageal, serious esophageal, and extraesophageal. Benign esophageal symptoms include recurrent emesis, feeding refusal, and arching. Serious esophageal symptoms include stricture, erosive esophagitis, and Barrett esophagus. Extraesophageal symptoms include poor weight gain, apnea with associated bradycardia, wheezing, asthma, aspiration, otitis media, sinusitis, hoarseness, dental erosions, chronic sore throat, chronic stridor, blood-tinged emesis, anemia, chronic cough, and recurrent pneumonia (Gold, 2004; Henry, 2004).

There are a number of etiologic factors that increase an infant's propensity to higher frequency of GER (Milla et al., 2002; Hassall, 2005). These factors can be divided into those associated with normal infant physiology, abnormal underlying physiology, and iatrogenic causes. Term and preterm neonates normally have anatomic and physiologic features that increase their risk of GERD, including a shorter and more narrow esophagus, delayed gastric emptying, and a shorter lower esophageal sphincter that is both

frequently superior to the diaphragm and periodically relaxes independent of swallowing (Henry, 2004). Beyond the anatomic considerations, infant diets consist primarily of liquids (breast milk or formula), which are provided frequently and in larger relative volume because of their feeding schedules and high caloric requirements (Henry, 2004). Examples of factors that are associated with abnormal underlying physiology include inhibition of esophageal body peristalsis with relaxation of the lower esophageal sphincter, decreased lower esophageal sphincter resting tone, gastric distention, delayed esophageal clearing, hiatal hernia, and neurologic impairment (Gold, 2004). Examples of iatrogenic factors that increase risk for GERD include supine positioning during feeds and adjuvant treatments of neonates such as caffeine for apnea.

Symptoms of older children and adults are distinct from those in infants. Older children may experience abdominal discomfort or pain, early morning nausea, eructation that burns, substernal chest pain, heartburn, recurrent emesis, and extraesophageal symptoms including apnea/bradycardia, wheezing/asthma, otitis media, hoarseness, dental erosions, chronic sore throat, chronic cough, esophagitis, esophageal stricture, Barrett esophagus, and recurrent pneumonia (Gold, 2004; Hassall, 2005). A natural history study of children aged 2 to 17 years (mean age 6.8 years) by Ashorn et al. found that in children the most common symptom was recurrent abdominal pain and was reported in 63% of patients (Ashorn et al., 2002).

Diagnosis

Objective Measures

A variety of diagnostic tests have been employed to augment clinical history and physical examination in the diagnosis of GERD, though none has sufficient accuracy to act as the reference standard. Moreover, data are lacking to determine the sensitivity, specificity, positive predictive value, or negative predictive value of these tests. These tests include 24-hour pH monitoring, combined 24-hour pH multichannel intraluminal impedance (pH-MII), manometry, endoscopy, gastric scintigraphy (gastric emptying study), and barium swallow (Mauritz et al., 2011).

24-Hour pH Monitoring

24-hour pH monitoring is frequently used in the diagnosis of GERD. This is seen as an objective measure of acid exposure in the esophagus that includes four elements: the total time the esophagus experiences a pH higher than 4, the number of episodes of pH higher than 4, the percentage of time at a pH higher than 4, and the longest period of pH higher than 4. Often, the studies are performed with at least two channels—one in the distal esophagus, and one in the proximal—to ascertain the level of esophageal acid exposure as well. Studies of the usefulness of this test in children and infants are mixed. A study by Ashorn et al. found that correlation between abnormal pH-monitoring results and histologic inflammation found on endoscopic examination with biopsy was poor (Ashorn et al., 2002). Tovar et al. examined patients who underwent antireflux operations in the setting of normal pH studies (Tovar et al., 1991). The authors studied 14 children with a diagnosis of GERD, based on clinical symptoms such as vomiting, dysphagia/pain, and respiratory tract disease who underwent an antireflux operation for GERD, but had normal manometry. These patients were compared with 14 controls who also had normal manometry and who also had a workup for GERD but were ultimately found not to have indications for an antireflux

operation. The authors found that those children who underwent an antireflux operation had symptom resolution, thus concluding the possibility of false-negative results of manometry. A study by Gorenstein et al. examined findings on pH monitoring between children with respiratory, gastrointestinal, and mixed symptoms of GERD and found only that children with gastrointestinal (GI) symptoms had a slightly higher percentage of time with pH higher than 4 and that the longest episode was on average 4 minutes longer than the comparison groups (Gorenstein et al., 2003). These findings suggest that while pH monitoring may measure esophageal acid exposure, this metric alone in children is poorly correlated with symptoms and signs thought to be associated with the diagnosis of GERD.

24-Hour Combined pH and Multichannel Intraluminal Impedance

The pH-MII exam combines abnormal pH detection in the esophagus with impedance and, specifically, measurement of lower esophageal sphincter pressure. Multichannel intraluminal impedance adds the ability to detect bolus movement through the esophagus. It is important in evaluation of GERD because it can examine for acid and nonacidic reflux. In a direct comparison of the 24-hour pH probe and the pH-MII, Wu et al. determined that the pH-MII detected significantly more reflux episodes than the pH probe alone, with better symptom correlation (Wu et al., 2013). Despite the theoretical benefit of pH-MII, Rosen et al. noted that findings on pH-MII did not correlate with postantireflux procedure outcomes (Rosen et al., 2010). In contrast, Berquist et al. found that the mean frequency of GERD episodes prior to the antireflux procedure was significantly higher than for controls, and following the operation it was significantly lower (Berquist et al., 1981).

Manometry

Manometry measures lower esophageal sphincter pressure and length. Manometry may be especially useful for the diagnosis of esophageal motility disorders. The use of high-resolution esophageal manometry, while common in adults, has been more slowly adopted in pediatric patients (Goldani et al., 2010).

Gastric Scintigraphy

Historically, scintigraphy of the stomach (gastric emptying) was an essential component of the work-up and diagnosis of GERD for some providers, specifically to identify the presence of delayed gastric emptying as an etiology for reflux. Scintigraphy is a nuclear medicine radiologic study in which patients ingest technetium formula, with serial images captured over time measuring movement of contrast either out of the stomach or retrograde into the esophagus. In one study, the authors performed gastric scintigraphy on 51 patients with documented GER and compared the results with those of 24 controls without GER and found a statistically significant difference in gastric emptying times (Knatten et al., 2013). Other studies have had mixed results, and a well-designed prospective study of the use of gastric scintigraphy and gastric emptying procedure in the setting of delayed gastric emptying is lacking. Perhaps the best use of this examination in patients suspected of GERD is those with aspiration pneumonia in which identification of technetium in the lungs during the examination is fairly sensitive and specific for aspiration (Sherman et al., 2009).

Upper Gastrointestinal Series

Upper GI series may be used to define luminal anatomy by following a bolus of contrast through the esophagus, stomach, and duodenum.

It is optimally utilized to evaluate for diagnoses such as achalasia, nutcracker esophagus, and other anatomic anomalies that may be associated with symptoms related to GERD. In the neonatal population, a common diagnosis with a significant symptom overlap with GERD is an anomaly of malrotation, which is best diagnosed with an upper GI series. For the evaluation of classic reflux, the upper GI series performs poorly compared with other tests such as pH monitoring. In their retrospective cohort study of 656 patients with a mean age of 17.4 months (range 0.15–228 months) who underwent an antireflux procedure and had a preoperative upper GI series, Valusek et al. found that an upper GI series altered clinical management in only 4% of cases when attempting to delineate pathologic reflux (Valusek et al., 2010). The utility of the study is likely higher if considering patients who had a work-up for GERD and were found on upper GI series to have malrotation, requiring a Ladd procedure rather than an antireflux procedure.

Indications for Medical and Surgical Management of Gastroesophageal Reflux Disease

Medical or surgical intervention should be targeted only to those infants with troublesome symptoms or complications. Measurement and success of treatment must be resolution of the initial indication. Consensus definition of pediatric GERD was performed by a panel of experts and published in 2009 (Sherman et al., 2009). The experts defined GERD as the following: GERD in pediatric patients is present when reflux of gastric contents is the cause of troublesome symptoms and/or complications. Importantly, regurgitation was defined as the passage of refluxed contents into the pharynx, mouth, or from the mouth, and while it is a characteristic symptom of GERD, it is neither necessary nor sufficient for the diagnosis of GERD (Sherman et al., 2009). The panel also noted that bilious emesis should not be diagnosed as GERD.

Options for Interventions

Pharmacologic Agents

The two main classes of pharmacologic agents used for the treatment of GERD are acid buffering or suppressant and prokinetic medications. Acid buffering and suppressant medications include antacids, histamine receptor antagonists, and proton pump inhibitors. Antacids decrease the acidic gastric environment by acting as a buffer. In theory, the elevation in pH allows for mucosal healing and relief of symptoms. In general, however, these medications are not recommended in infants or children with GERD since they have been shown to cause aluminum toxicity and milk-alkali syndrome (Drug and Therapeutics Bulletin, 2010; Lightdale et al., 2013).

Histamine receptor antagonists block the histamine receptor on parietal cells in the stomach thus reducing acid release. While a randomized controlled study has found significant improvement in erosive esophagitis and acid exposure with nizatidine compared with placebo in children, tachyphylaxis is common (Simeone et al., 1997; Lightdale et al., 2013). A nonrandomized, multicenter observational prospective study of consecutively admitted very low birth weight infants compared those who did and did not receive ranitidine (Terrin et al., 2011). The authors found that infants who received ranitidine were five times more likely to have an infection and had an over sixfold higher risk of necrotizing

enterocolitis and significantly higher mortality compared with controls.

Proton pump inhibitors decrease acid secretion by blocking the hydrogen/potassium (H^+ / K^+) ATPase on the gastric parietal cell. Compared with histamine receptor antagonists, proton pump inhibitors are more potent by directly blocking acid secretion and have a resultant increase in pH higher than 4 for a longer period of time (Lightdale et al., 2013). In a prospective study of 78 consecutive children (mean age 40.6 months, standard deviation 36.4 months, range 1–181 months) referred to the pediatric department of GI endoscopy and motility at the University of Naples in Italy, proton pump inhibitors and histamine H_2 -receptor antagonists were compared (Ummarino et al., 2012). Proton pump inhibitors were found to be superior in extraesophageal symptom resolution. Although proton pump inhibitors may be more effective, none has been approved for use in infants (aged less than 1 year), and the indication for treatment must be specific since this class of medication has not been shown to reduce symptoms of irritability (Moore et al., 2003; Griebel, 2010).

Four proton pump inhibitors have been studied with prospective, randomized controlled trials. A multicenter randomized, double-blind, placebo-controlled trial of the proton pump inhibitor lansoprazole in infants aged 1–12 months weighing over 2 kg, with symptomatic GERD (defined as documentation of crying within 1 hour of at least 25% of feeds) and at least 1 week of nonpharmacologic management of symptoms, found no statistically significant differences in symptom improvement (Orenstein et al., 2009). A randomized, double-blind, placebo-controlled, crossover design trial of omeprazole of 10 preterm infants with symptoms such as feeding problems, vomiting, irritability, and weight loss thought to be related to GERD found that while gastric and esophageal acidity decreased significantly in the omeprazole group, there were no significant differences in symptom frequency (Omari et al., 2007). A multicenter, randomized double-blind, placebo-controlled parallel-group study of esomeprazole saw no difference in the time to medication discontinuation related to symptom-worsening between groups (Winter et al., 2015). A study by Winter et al. initially treated 128 infants aged 1 to 11 months with pantoprazole then randomized 106 of those patients in a double-blind, placebo-controlled evaluation of pantoprazole (Winter et al., 2010). The authors found that while symptoms decreased significantly during the open label phase of the trial when all patients received pantoprazole, there was no significant increase in mean weekly symptom scores when the patients were randomized to receive pantoprazole or placebo. Additional risks potentially associated with acid suppression medications include community-acquired pneumonia, gastroenteritis, candidemia, and necrotizing enterocolitis in preterm infants (Van der Pol et al., 2011; Lightdale et al., 2013). No proton pump inhibitor has US Food and Drug Administration approval for infants younger than 1 year of age with GERD, though off-label use is likely common (Drug and Therapeutics Bulletin, 2010; Griebel 2010).

Prokinetic agents are another class of medications used to treat symptoms of GERD. The proposed mechanism of action for prokinetic agents in the treatment of GERD includes increased lower esophageal sphincter pressure and increased gastric emptying. The most common prokinetic agent used is metoclopramide, although significant adverse reactions include drowsiness, extrapyramidal reactions, and restlessness. Although medical management is recommended as a first-line treatment for GERD, there are no medications that have US Food and Drug Administration approval for use in infants, and definitive prospective data in infants are

lacking (Rudolph, 2003; *Drug and Therapeutics Bulletin*, 2010; Greene and Moeny, 2010). Despite the lack of approval, prescriptions have been rising (Greene and Moeny, 2010).

Surgical Intervention

A multitude of surgical interventions have been described for the treatment of GERD. Various technical approaches include, but are not limited to, open, laparoscopic, and robotic antireflux procedures. Technical variations range from partial and full fundoplication. For children with significant neurologic impairment and severe refractory GERD, some surgeons have advocated for an esophagogastric separation (Islam et al., 2004; Boubnova et al., 2009; Zaidi et al., 2010; Cundy et al., 2013). More recently, newer operations, that are not yet mainstream, have been attempted such as lower esophageal sphincter buttressing via magnets, endoluminal fundoplication, and sclerosis. There appears to be geographic and institutional variation in the type and approach of antireflux operative intervention (Goldin et al., 2009; Nusrat and Bielefeldt, 2014). The multitude of approaches and technical variations of antireflux procedures speaks to the fact that there is no single operation that has been shown to be consistently superior. In general, antireflux operations are designed to correct and improve the anatomy of the lower esophageal sphincter and diaphragm. The most commonly used procedure, called a *Nissen fundoplication*, includes several components. It increases the intra-abdominal esophageal length, thereby increasing external pressure and augmenting the function of the lower esophageal sphincter. Wrapping the fundus of the stomach around the lower esophageal sphincter further strengthens the lower esophageal sphincter since they share nerve supply and contract simultaneously to recreate the angle of His, thus diverting gastric content away from the esophagus, effectively repairing the diaphragmatic crura.

All operations that address symptoms of GERD, regardless of approach, have been noted to be associated with both short-term and long-term complications. A study of laparoscopic Nissen fundoplication in infants and children weighing less than 5 kilograms found that 71% required a postoperative intensive care unit stay for an average of 2 weeks, and 31% required postoperative mechanical ventilation for an average of 12 days (Shah et al., 2010). Complications from the procedure in this cohort were noted to include recurrent reflux, gastric perforation, and hemorrhage (Shah et al., 2010). A multiinstitutional review found that younger age at antireflux procedure was significantly associated with the need for a redo fundoplication (Baerg et al., 2013). Young age has also been associated with a lower rate of hospitalization after antireflux procedure (Goldin et al., 2006).

Comparison of laparoscopic and open Nissen fundoplication is limited though the current literature indicates that the laparoscopic approach is likely a safe alternative (Blewett et al. 2002; Rangel et al., 2003). Comparison of partial and complete fundoplication shows a lack of well-designed studies, so currently the two approaches appear to have comparable effectiveness for control of the symptoms of GERD in neurologically normal children (Mauritz et al., 2013).

Conclusion

Despite the frequency with which children, and especially neonates, are diagnosed with GERD, there is significant complexity in

obtaining objective proof that GERD is responsible for any presenting symptom. It is important to remember that many of the symptoms associated with GERD are neither sensitive nor specific to the diagnosis. It is therefore critical to understand that one's goal is to treat the symptom or sign attributed with GERD and not necessarily the GERD itself.

The Intestinal Microbiome

JOSEF NEU

KEY POINTS

- Evidence is accumulating that the fetal environment is not sterile, nor is human milk, and that the early exposure to microbes may play an important role in subsequent health.
- Manipulation of the early microbiome with antibiotics (given prenatally or postnatally), mode of delivery, and other environmental conditions may alter the delicate balance between the microbes and the human host and result in disease.
- Metabolites produced by microbes as well as by the host–microbial interactions may play a role in the immunologic development of the host.

Since the initiation of the Human Microbiome Project in 2007 (Turnbaugh et al., 2007), there have been marked advances in our knowledge of the interactions between humans and their microbial environment. It is becoming clear that the vast majority of bacterial microbes, the “microbiota,” that interact with humans are not pathogens but rather commensals and symbionts, many of which play a major role in health. The interaction of microbes with the pregnant mother, the fetus, neonate, and infant appears to be especially important for future development, health, and disease. This chapter provides an overview of current knowledge of the microbiome, defined as the combined genetic material of the microorganisms in a particular environment, and how it relates to the fetal–maternal unit, the neonate, and subsequent health. Included will be a brief description of new and developing technologies that are rapidly advancing this field. Also described are various aspects of the microbiome during intrauterine and fetal life as it relates to premature labor, premature and term infant disease entities such as necrotizing enterocolitis (NEC) and sepsis, basic interactions between the microbiome and the intestinal immune system, and its bioreactor/nutritional function. Perturbations that affect the human–microbial ecosystem—the “holobiont” (Gilbert, 2014a)—such as antibiotics and other drugs, mode of delivery, and diet are also discussed.

Historical Perspectives

Beyond Culture

New technologies using nonculture-based methods have shown that the majority of microbes in the intestine have not yet been

cultured. Advances in nonculture DNA sequencing–based technologies that evaluate taxa of microbes residing in various niches of the human body are providing us with the knowledge that when one evaluates the number of genes or cells in the average human, only 10% are mammalian, and the rest are microbial (Xu and Gordon, 2003; Gill et al., 2006). We now know that there are more than 2000 taxa of bacterial microorganisms within our bodies, most of them residing in our intestines. The recent development of nonculture-based techniques to evaluate microbial DNA is providing new insights into the relationship that exists between microbes and their mammalian hosts, especially the microbes that reside in the gastrointestinal (GI) tract (Gill et al., 2006), where they have a profound effect on digestive physiology, development, and health of the host (Stappenbeck et al., 2002; Xu and Gordon, 2003; Hooper, 2004; Dethlefsen et al., 2007). During evolution, the host has developed protective responses against foreign microbes but at the same time has developed a mechanism that provides a welcome and mutually beneficial environment for microbes and the host (Hooper and Gordon, 2001; Hooper et al., 2002; Bäckhed et al., 2004, 2005; Hooper, 2004).

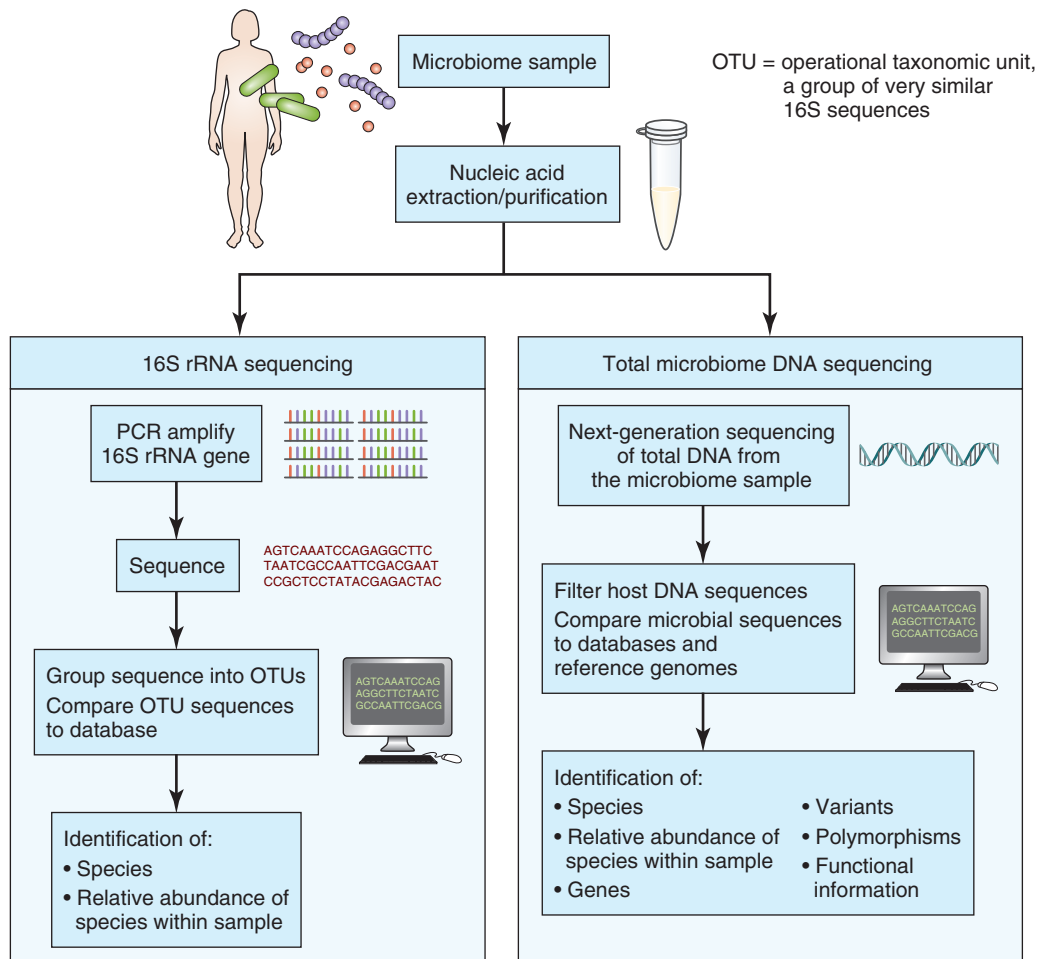

Technologies

Currently, there are two nonculture-based methods (Fig. 75.1) commonly used for characterization of the microbiome (the collection of genes in the microbiota):

- Small-subunit ribosomal ribonucleic acid (rRNA) studies, in which the 16S rRNA variable gene sequences are used as phylogenetic markers to define which lineages are present in a sample
- Metagenomic sequencing studies, in which community DNA is subject to shotgun sequencing (Fodor, 2014)

The 16S rRNA is a part of the ribosomal RNA that is used for phylogenetic studies as it is highly conserved between different species of bacteria and archaea. In addition to highly conserved primer binding sites, 16S rRNA gene sequences contain hypervariable regions that can provide species-specific signature sequences useful for bacterial identification. As a result, 16S rRNA gene sequencing has become prevalent in medical microbiology as a rapid, accurate alternative to phenotypic methods of bacterial identification.

In this technique, DNA is extracted from fecal samples; the targeted 16S rRNA genes (usually the V1–3 or V4 region) are amplified using universal polymerase chain reaction primers capable of efficient annealing to rRNA genes from most bacteria. Based on the degree of nucleotide similarity (usually between 95% and

• **Fig. 75.1** Two Commonly Used Methods of Microbiome Analysis. 16S rRNA sequencing is the faster and less expensive method. It provides information about the relative abundance of taxa present in a sample (“who is there”). Total microbiome DNA sequencing analyzes the total DNA from a sample, but in addition to providing taxonomic information, it can also provide functional information (“what the microbes are doing”). PCR, Polymerase chain reaction; rRNA, ribosomal ribonucleic acid. (Adapted from: <https://www.neb.com/tools-and-resources/feature-articles/addressing-challenges-in-microbiome-dna-analysis>.)

99%) sequences are then separated into operational taxonomic units that form the basis for comparisons between samples. This technique is primarily used to provide taxonomic information (“who’s there”) rather than function data (“what are they doing”) that can better be provided by metagenomic shotgun sequencing (Fodor, 2014).

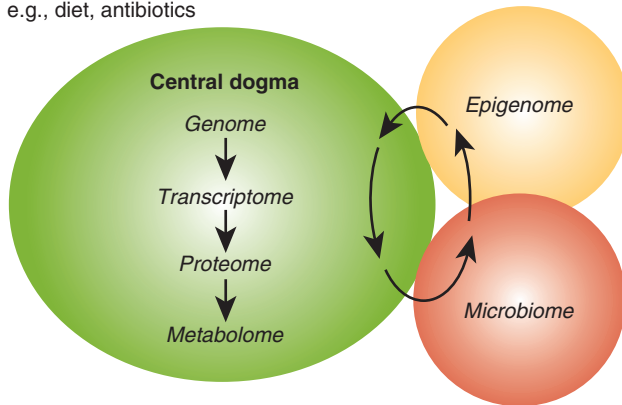

Metagenomics is the study of genetic material recovered directly from environmental samples that enables studies of organisms that are not easily cultured in a laboratory as well as studies of organisms in their natural environment. Studies use shotgun sequencing to get (mostly) unbiased samples of all genes from all members of sampled communities (Fodor, 2014). This technique provides much more information with regard to total microbial gene function but is also much more expensive than the 16S rRNA-based techniques. However, these techniques are rapidly evolving, and the costs are becoming much less prohibitive.

Other “Omics”

The aforementioned discussion underlines that fact that the human organism is composed and controlled not only by its mammalian

genetic complement (human genome comprising approximately 23,000 genes) but also the microbial genetic component (the microbiome—sometimes termed the “second genome” comprising at least 100 times as many genes as those derived from the human sperm and egg). These synergize with environmental factors such as diet to comprise the epigenome, proteome, transcriptome, metabolome, and epigenome (Fig. 75.2). These correspond to various microbial functions, and the technologies for their analysis are rapidly evolving. Transcriptomics will allow for the detection of more specific microbial gene products as will metabolomics and proteomics. It is believed that the microbiome plays a prominent role in human metabolism because microbes produce harmful and beneficial small molecules for humans such as vitamins, polyphenols, cholesterol, and short-chain fatty acids (SCFAs) (Nicholson et al., 2012). A recent comparison of plasma profiles in conventional and germ-free mice showed a strong correlation between the plasma metabolite levels and the microbes present (Wikoff et al., 2009). Future studies may find significantly different metabolite patterns in urine and fecal samples from the mothers who deliver prematurely compared with those delivering at term when we employ systems biology pathway mapping.

Environmental influences:
e.g., diet, antibiotics

• **Fig. 75.2** The Central Dogma of the Human Genome. DNA is transcribed to RNA, which codes for protein, which in turn produces metabolites. The microbiome undergoes similar transformations, but metabolic products from the microbiome may be epigenetically active and modulate the human genomic pathway.

Epigenomics will allow for the integration of the techniques for microRNA, DNA methylation, and histone modification analysis in the amplification and silencing of host genes and gene products. In addition, analysis of microbe–host gene interactions is an area that is receiving considerable attention (Duca et al., 2014; Sanchez et al., 2015; Sun and Hu, 2016).

Alterations in the intestinal microbiome have been linked to obesity, autoimmune diseases, allergy asthma, eczema, and even the induction of premature labor, some of which are described in this chapter (Chang and Neu, 2015). The role of intestinal microbes, especially during early development in these highly interrelated components, is clearly related to human health and disease and is an exciting area for future investigation (Turnbaugh and Gordon, 2008). Use of these developing multiomic technologies and their interpretation using sophisticated “big data” approaches will be keys to progress in these areas.

Actions of the Intestinal Microbiome

The human metaorganism has been described as a holobiont, which has been defined as a “super or meta-organism that adjusts and transforms itself according to environmental changes causing evolution of the entire entity” (Gilbert, 2014a, 2014b). It contains a prokaryotic component in the intestine that comprises nearly 10^{14} cells that weigh over 1 kg in the human adult. There is a marked aboral gradient in the number and types of microbes in different regions of the intestine, with 10^{11} in the ascending colon and 10^{7-8} in the distal ileum and 10^{2-3} in the jejunum. A better understanding of many of the actions of the microbiota in the GI tract (Box 75.1) is emerging. Although there is overlap with function between intestinal regions, the small intestine is primarily involved with immunoreactivity and immune functions, and the large intestine plays more of a bioreactor/metabolic function (Neish, 2009).

Intestinal Inflammation and Immune Function

The intestinal microbes represent a key regulatory check point for the development of the adaptive immune system and also for the innate inflammatory response. The intestinal epithelium relies on

• BOX 75.1 Functions of Microbiota

1. Metabolic/nutritional
 - a. Vitamins
 - b. Short-chain fatty acids
2. Intestinal development

3. Exclusion of pathogens
4. Innate immune regulation
 - a. Modulation of inflammatory response
 - b. Recognition and destruction of pathogens
5. Adaptive immune regulation
 - a. Development of tolerance

toll-like receptors (TLRs) to act as an interface between the luminal microbiota and signal transduction pathways. TLRs are cell-surface receptors that recognize specific microbial ligands, from both pathogens and commensals, enabling the innate immune system to recognize nonself and activate both innate and adaptive immune responses (Takeda et al., 2003). The epithelium and resident immune cells are dependent on commensal bacteria, which secrete molecules such as lipopolysaccharides and lipoteichoic acid. These, in turn, interact with a population of surface TLRs, wherein signaling enhances the ability of the epithelial surface to withstand injury while at the same time priming the surface for enhanced repair responses (Madara, 2004; Strober, 2004). Therefore disrupting TLR or removing the TLR ligands (bacteria) will decrease the ability of the intestinal surface to protect and repair itself after occurrence of an inflammatory or infectious insult (Rakoff-Nahoum et al., 2004).

In addition to the effects of the microbiota on the innate immune system, there are significant effects on the adaptive responses as well. Regulatory T cells (T_{regs}) are able to dampen inflammation after microbial infection. Subsets of T_{regs} are generated in the gut from naïve T cells (“inducible” T_{regs}). This can be important because these produce the anti-inflammatory cytokine interleukin-10 (IL-10) (Lee and Mazmanian, 2010). Several bacteria have been shown to induce T_{regs} and IL-10 production in the gut (O’Mahony et al., 2008). Members of the genus *Bacteroides* contain the bacterial molecule polysaccharide A, which directs the cellular and physical development of the immune system via T_{regs} and is thereby considered protective because of its ability to suppress inflammation-driven host pathology. This is an area of considerable current investigation because of its likely role in numerous disease entities such as type 1 diabetes and other autoimmune diseases.

The Bioreactor Function

Complex carbohydrates are poorly digested by the human digestive system and require microbiota for breakdown via fermentation. In the distal intestine, primarily the colon, a bioreactor function of the intestinal microbes occurs and is highly amenable to study using metabolomic methodologies (Nyangale et al., 2012). The end products of fermentation include SCFAs such as acetate, propionate, and butyrate. The SCFAs influence various aspects of intestinal physiology beyond being a caloric source (Rios-Covian et al., 2016). They possess differentiating and growth-promoting activities that are thought to be related to their effects on histone deacetylase activity and also have epigenetic effects. They have

immunomodulatory effects and major effects on the interepithelial tight junctions. Examples of processes that can be mediated via this bioreactor process include how changes in the microbial population affect obesity, noninsulin-dependent diabetes, and atherosclerosis (Ley et al., 2006). In the distal intestine, primarily the colon, undigested complex carbohydrates in postweaned individuals are primarily vegetable fibers, whereas in the infant, they are primarily undigested human milk oligosaccharide (Bode, 2015) and, in some cases, primarily very preterm infants, nonabsorbed lactose (Kien et al., 2002). This is of importance for preterm infants, who are thought to have lower activities of lactase than term infants (Antonowicz and Lebenthal, 1977). Even if there is a deficiency of lactase activity in the small intestine of very premature neonates, a healthy distal intestinal flora is able to “salvage” some of the undigested lactose into absorbable and usable 2–4 carbon energy sources (Kien, 1996).

There is a large effect of the microbiota on mammalian plasma biochemistry. Mass spectrometry-based profiling of serum from germ-free and nongerm-free mice demonstrates that a significantly large number of chemical species found in systemic circulation arise because of the presence of the microbiota. These microbe-related metabolites can be beneficial or toxic to the host (Wikoff et al., 2009).

Development of the Intestinal Microbiome

The Nonsterile Fetal Environment

The dogma that the fetus resides in a sterile environment and that the newborn only attains its microbiota after exposure to the extrauterine environment is being effectively challenged (Funkhouser and Bordenstein, 2013; Reid et al., 2015; Romano-Keeler and Weitkamp, 2015; Rautava, 2016). It has been known for decades that even without a ruptured amnion, amniotic fluid frequently contains significant levels of bacteria (Bobitt and Ledger, 1977).

Additionally, studies using nonculture-based techniques further reveal the presence of microbes in placenta, amniotic fluid, and meconium (Han et al., 2009; DiGiulio, 2012; Moles et al., 2013; Aagaard et al., 2014; Ardisson et al., 2014; Payne and Bayatibojakhi, 2014), and the taxonomy of these microbes differs, depending on the stage of fetal maturity (Aagaard et al., 2014; Ardisson et al., 2014). The finding that a greater degree of prematurity is directly related to the bacterial DNA load in amniotic fluid suggests a relationship between preterm delivery and microbial load (DiGiulio et al., 2008; DiGiulio, 2012). This relationship is further causally implicated by microbial DNA concentrations that directly correlate with levels of white blood cells and IL-6 in the amniotic fluid. This suggests a pathophysiologic sequence of increased microbial load, inflammation, and preterm birth (DiGiulio et al., 2008; Han et al., 2009; Combs et al., 2014). Intrauterine “infection” and a subsequent fetal inflammatory response have been linked to prematurity, brain, lung, and eye disease after preterm birth (Dammann et al., 2002; Dammann and Leviton, 2006). One hypothesis relates swallowed amniotic fluid microbes to an intestine-derived inflammatory response and preterm labor and neonatal morbidities (Fig. 75.3). In this hypothesis, amniotic fluid microbes (presumably derived from ascending vaginal microbes) are swallowed by the fetus. These microbes subsequently reach the highly immunoreactive fetal GI tract, where a fetal-derived inflammatory response syndrome (FIRS) incites an inflammatory response that leads to premature labor and neonatal morbidity.

Studies interrogating the placental microbiome show a relationship between different taxa of microbes and level of prematurity (Aagaard et al., 2014). Of interest, a similarity between placental microbes and oral microbial DNA sequences from a database of nonpregnant women was found. It was also found in these studies that *Escherichia coli* was one of the largest taxa represented in the placental samples (Aagaard et al., 2014). It is of interest that this is a common resident of the intestine and thus suggests a maternal intestinal origin.

• **Fig. 75.3** Hypothetical Pathway Through Which Amniotic Fluid Microbes Are Swallowed by the Fetus. These microbes (presumably derived from ascending vaginal microbes) subsequently reach the highly immunoreactive fetal gastrointestinal tract, where a fetal-derived inflammatory response syndrome incites an inflammatory response that leads to premature labor and neonatal morbidity. *FIRS*, Fetal-derived inflammatory response syndrome.

The mechanisms of how the maternal–fetal microbes relate to preterm birth are unclear, but evidence suggests that microbes in the fetal intestine may play a role (see Fig. 75.3). This is supported by (1) the well-known relationship of amniotic fluid microbial colonization, FIRS, and premature labor (Bobitt and Ledger, 1977; Romero et al., 1988, 1998, 2007; Andrews et al., 1995; Goldenberg et al., 2008), (2) the fact that the fetus swallows large quantities of amniotic fluid during the late second and third trimesters of pregnancy (Brace and Wolf, 1989; Gilbert and Brace, 1993), and (3) the capability of systemic inflammation to be derived from the GI tract (Carrico et al., 1986), especially by the fetus (Nanthakumar et al., 2000).

Maternal Intestinal Host–Microbial Interactions

Maternal intestinal host–microbial interactions contribute to maternal metabolism during pregnancy and suggest that “dysbiosis” (defined as a microbial imbalance on or inside the body) in the maternal GI tract may influence the fetal inflammatory mediators, T-cell effector, and tolerizing regulatory cells and metabolic patterns that lead to preterm delivery. The mother immunologically recognizes the fetus as self via a balance of these T cells and maintains tolerance, but dysbiosis may affect this balance, leading to a response that leads to prematurely eliminating the fetus from the intrauterine environment (Trowsdale and Betz, 2006). The effects of the pregnant woman’s diet on the microbiome, epigenome, and metabolome affecting subsequent disease in the offspring have been recently shown in studies where feeding mice a high-fiber diet yielded a distinctive gut microbiota, which increased the levels of the SCFA acetate and markedly decreased allergic disease in the offspring (Thorburn et al., 2015). Thus an evaluation of the mother’s diet and how it affects the microbiota may reveal approaches to decrease morbidity and preterm birth by modulation of the maternal microbiome by dietary means during pregnancy. This could be via altered metabolites and/or inflammatory mediators, which should be detectable in the maternal stools, blood, and/or urine.

Accumulating evidence supports that innate immune cells such as neutrophils, macrophages, and mast cells mediate the process of labor by releasing proinflammatory factors such as cytokines, chemokines, and matrix metalloproteinases (Lusyati et al., 2013). T-cell subsets and B cells (adaptive immune cells) participate in the maintenance of feto–maternal tolerance during pregnancy, and an alteration in their function or abundance may lead to preterm labor (Challis et al., 2009; Gomez-Lopez et al., 2014). Marked elevations of peripheral blood CD4⁺CD25⁺ Forkhead Box P3 (Foxp3⁺) T_{regs} are found during early pregnancy but decline during labor, either at term or preterm, suggesting their involvement in maintenance of pregnancy and initiation of labor (Xiong et al., 2010). Also, immune cells that bridge the innate and adaptive immune systems such as dendritic cells may also participate in the pathophysiology of preterm labor. A balance between innate and adaptive immune cells is required in order to sustain pregnancy; an alteration of this balance will lead to labor (Gomez et al., 1998; Gomez-Lopez et al., 2014).

The Fetal–Maternal Microbiome Source

There is a gap in our knowledge of the source of the placental/fetal microbiome. Potential sources are illustrated in Fig. 75.4.

Vaginal microbes have been implicated in induction of preterm labor (McGregor et al., 1994; White et al., 2011; DiGiulio, 2015). However, another study contradicts the notion that microbes

• **Fig. 75.4** Potential Origins of the Fetal/Placental Microbiome. These include a hematogenous route from the oral cavity or intestinal tract or an ascending route via translocation through the chorio–decidual membranes.

originating from the vagina are the origin of preterm labor (Romero et al., 2014). Another potential source is from the maternal mouth (periodontal tissue) (Madianos et al., 2013). One study interrogated the placental microbiome from infants born at various gestational ages and found associations between placental microbial taxa, preterm birth, and infections early in pregnancy (Aagaard et al., 2014). Intriguingly, a similarity between the placental microbes and those found in the mouth from a human microbiome database was also found, but the samples were not derived from the same individuals; thus direct comparisons between microbial sources are not possible. In addition, the placental taxa that were most highly represented in that study were *E. coli*, which are intestinal microbes. More recent studies (Shiozaki et al., 2014) evaluated maternal stool and vaginal samples from three groups of women who (1) delivered term babies without preterm labor, (2) delivered term babies but with preterm labor, and (3) had preterm birth. Significant differences in microbial taxa were found in fecal samples between these three groups: *Clostridium*, *Lactobacillus*, and *Bacteroidetes* clusters differed significantly. As in a study of Romero et al. (2014), no differences were found in the vaginal microbiota between these three groups, suggesting the maternal intestinal tract is the source of fetal microbes linked to preterm birth. Importantly, it is known that microbes can translocate via the maternal GI tract in rodents (Jimenez et al., 2008) and humans (Rautava et al., 2012) and that food-borne *Listeria* can translocate from the maternal intestine to the fetus (Vazquez-Boland et al., 2001). Thus finding the major sources of the microbes that relate to preterm labor and other morbidities related to inflammation will be a major challenge.

Knowledge of where the fetal–maternal microbes are derived from is critical if we are to propose specific microbial-based therapeutic interventions to prevent spontaneous preterm birth. The origin of these bacteria may differ, depending on the bacterial taxa being considered. One could conjecture that the maternal intestine is a likely source of most of these microbes, but, as previously mentioned, ascending microbes from the vaginal tract and/or hematogenously derived oral microbes may also be involved. This requires more rigorous investigation by evaluating microbiota from various sources in the same mother–infant pair (placenta, vagina,

mouth, blood, maternal stool, and infant meconium) using 16S rRNA and metagenomic sequencing and newly developed bioinformatics source tracking tools.

The Infant Microbiome

Mode of Delivery

There is an association between mode of delivery—vaginal versus cesarean section (C-section)—and the subsequent composition of the microbiome of the developing infant (Salminen et al., 2004; Biasucci et al., 2008; Dominguez-Bello et al., 2010; Cabrera-Rubio et al., 2012; Azad et al., 2013; Jakobsson et al., 2014). This could have significant public health implications for areas where the rate of C-section delivery without strong medical indications is very high, since C-section delivery is associated with greater risks of various adverse outcomes (Cardwell et al., 2008; Decker et al., 2010; Blustein et al., 2013; Bernardi et al., 2015; Miettinen et al., 2015; Mueller et al., 2015). These epidemiologic studies are fraught with confounding factors, but such associations need to be seriously considered. The causal relationship between C-section delivery and some of these adverse outcomes remains to be rigorously established. Whether breastfeeding, as suggested by small studies (Azad et al., 2013; Madan et al., 2016), may reverse the microbiome toward one that is similar in composition and function as that resulting from vaginal delivery remains unclear. Studies showing partial restoration of the microbiota of C-section-born infants via vaginal microbial transfer using vaginal swabs are intriguing in that they do suggest that the vaginal microbiota can be restored in C-section-delivered infants (Dominguez-Bello et al., 2016). However, the safety of inoculating the newborn with unknown vaginal microbes has not been adequately investigated, and thus this method is not ready for routine use.

Intestine-Derived Inflammation

A major role has been ascribed to systemic (usually intestine-derived) inflammation on several neonatal diseases, including NEC, chronic lung disease, intraventricular hemorrhage, periventricular leukomalacia, and hematopoietic abnormalities (Dammann and Leviton, 1999; Dammann et al., 2002).

Total Parenteral Nutrition

Practices that are common in the neonatal intensive care unit (NICU) include prolonged use of total parenteral nutrition (TPN), antibiotics, and H₂ blockers. In the premature infant, the reliance on parenteral nutrition may be highly significant in the promotion of intestinal inflammation (Kudsk, 2002). Whether this is partially due to stimulation of commensal bacterial growth is speculative, but studies in animals suggest an overgrowth of potentially pathogenic Proteobacteria when TPN is provided.

Summary

In this chapter, the newly emerging science of the microbiome as it relates to pregnancy and the neonate has been briefly discussed. Interactions between microbes and the host as well as microbial products and the host, especially early in life, may have

Effect of Diet

Human milk contains a wide array of biologically active components. Breastfed infants, unlike those who are formula-fed, have an intestinal ecosystem characterized by a strong prevalence of bifidobacteria and lactobacilli that appear to protect the preterm infant (Saavedra, 2001; Bourlioux et al., 2003). Several studies have shown the presence of microbes in human milk (Hunt et al., 2011; Collado et al., 2015). *Streptococcus* and *Staphylococcus* are highly represented, but other taxa are found as well. These studies suggest that microbes in an individual mother's milk are stable over time but differ markedly from one mother to the next, suggesting “personalization” of milk microbes. Among the numerous substances present in human milk, oligosaccharides are also present (Bode, 2012). These are thought to stimulate the development of bifidogenic microbes in the colon; hence human milk can be considered a symbiotic (Coppa et al., 2004) substance that has the properties of both a probiotic and prebiotic.

Effects of Antibiotics on Intestinal Microbiota

Administration of antibiotics to preterm infants is a common practice in NICUs due to the concern for sepsis. Several studies have shown a dysbiosis that occurs before the onset of NEC (Claud and Walker, 2001; Mai et al., 2011, 2013; Claud et al., 2013; Warner et al., 2016). More recently, it has been shown that the odds of developing NEC and mortality associated with NEC correlate with length of antibiotic exposure (Cotten et al., 2009; Alexander et al., 2011). However, in these studies it is unclear whether the initial degree of illness led to increased antibiotic usage or whether increased antibiotic usage led to increased degree of illness. The effects of antibiotic exposure on the microbial diversity of the intestine have been shown to last months after treatment is discontinued and have been shown to have long-lasting effects. Therefore it is critical that the routine overuse of antibiotics in the preterm be reconsidered.

Effects of H₂ Blockers

Premature infants have limited gastric acid secretion, which can be reduced even further with the use of H₂ blockers that have been linked to NEC in preterm neonates (Guillet et al., 2006; Terrin et al., 2012). H₂ antagonists have been used in the preterm population historically for treatment of apnea and bradycardia putatively because of gastroesophageal reflux, as well as in TPN while a patient is nil per os. It is thought that H₂ antagonists raise the gastric pH and reduce the bactericidal action in the stomach, which increases the total number of bacteria, promoting an overgrowth of potentially pathogenic bacteria (Gupta et al., 2013). These are among the most widely misused drugs in the NICU, and their routine use is discouraged (Ho et al., 2015).

transgenerational effects via epigenetic mechanisms. It should be clear that this is an area that is ripe for scientific and clinically relevant breakthroughs in the prevention and treatment of disease and maintenance of health, even beyond infancy.

Necrotizing Enterocolitis and Short Bowel Syndrome

PATRICK J. JAVID, KEVIN M. RIGGLE, AND CAITLIN SMITH

KEY POINTS

- Necrotizing enterocolitis (NEC) is the most common gastrointestinal emergency in the neonatal intensive care unit and a leading cause of mortality among very low birth weight infants.
- Pathogenesis is multifactorial with the combination of impaired intestinal perfusion, abnormal bacterial colonization, impaired gut barrier function, and an immature, overactive immune response leading to intestinal inflammation, ischemia, and eventual necrosis.
- Medical management includes bowel rest, broad-spectrum antibiotics, and supportive care.
- Surgical options include primary peritoneal drainage or laparotomy with bowel resection.
- Mortality from NEC reaches 50% in patients that require surgery, hence preventative measures such as breast-milk feeding and probiotic supplementation are important.

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is the most common gastrointestinal emergency in the neonatal intensive care unit (NICU) and is a leading cause of mortality among preterm and low birth weight infants. The incidence of NEC is inversely proportional to gestational age and birthweight, with NEC affecting between 7% and 10% of infants weighing more than 1500 g. Unfortunately, despite decades of research and improvements to NICU care, the mortality associated with NEC remains between 15% and 30% and is even higher for infants with NEC that require surgical intervention. NEC survivors may suffer from long-term complications such as intestinal stricture, short bowel syndrome (SBS), and neurodevelopmental impairment (NDI). Preventative strategies such as enteral feeding with human milk and probiotic supplementation are paramount for combating this deadly disease.

Epidemiology

NEC is primarily a disease of premature, low birth weight infants that develops days to weeks following the initiation of enteral feedings. In fact, over 90% of reported NEC cases are in premature infants (Uauy et al., 1991; Lemons et al. 2001). In term infants, the incidence of NEC is 0.5 per 1000 live births (Lemons et al.,

2001), and it is typically associated with other risk factors that decrease mesenteric perfusion such as congenital heart disease (CHD), hypoxemic perinatal events, intrauterine growth restriction, sepsis, or respiratory disease (Holman et al., 2006). Premature infants that have not been enterally fed may also develop intestinal perforation, but this disease process tends to be a different pathologic entity termed *spontaneous intestinal perforation* (SIP). SIP is an isolated intestinal perforation without additional signs of intestinal ischemia or necrosis typically seen in NEC. Unlike NEC, SIP most often presents before the initiation of enteral feeding in the first 2 weeks of life (Pumberger et al., 2002). Infants with SIP have much lower morbidity and mortality compared with those with NEC (Fisher et al., 2014). However, SIP and NEC can be difficult to differentiate before operative exploration, and many studies of clinical outcomes in NEC may include babies with both NEC and SIP.

Interestingly, the incidence of NEC varies greatly throughout the world. In the United States, the incidence of NEC in very low birth weight (VLBW) (<1500 g) infants ranges between 3% and 10% (Llanos et al., 2002; Guillet et al., 2006; Holman et al., 2006) compared with 28% in Hong Kong (Siu et al., 1998), 14% in Argentina (Halac et al., 1990), 7% in Austria (Eibl et al., 1988), 7% in Canada (Sankaran et al., 2004), 4% in Wales (Luig et al., 2005), and 1%–2% in Japan (Okuyama et al., 2002). There has been no appreciable decline in the incidence of NEC over the past two decades.

Risk Factors

Prematurity and Low Birth Weight

A number of risk factors have been found to be consistently associated with NEC, the most convincing being prematurity and low birth weight. Lemons et al. (2001) first reported the inverse relationship between birthweight and NEC. Recently, Jaksic and colleagues have elegantly demonstrated this relationship and how it relates to NEC-associated mortality, using data from the Vermont Oxford Network (Fitzgibbons et al., 2009). The incidence of NEC increases steadily from 3% in infants between 1250 g and 1500 g to 12% in infants between 500 g and 750 g. Concordantly, the mortality of those two groups is 16% and 42%, respectively.

Formula Feeding

Formula feeding is associated with an increased risk of NEC development, compared with feeding with human milk. Human milk has long been known to be the optimal nutritional source for premature infants and protective against the development of NEC (Lucas and Cole, 1990). There is now a large body of evidence to support these findings, including a recent Cochrane review that reports a 2.8-fold increase in the risk of NEC in premature infants fed with formula, compared with those fed with human milk (Cristofalo et al., 2013; Quigley and McGuire, 2014).

Congenital Heart Disease

Additional risk factors that have been associated with an increased rate of NEC include CHD and indomethacin use.

Prophylactic patent ductus arteriosus (PDA) closure was previously thought to carry up to a 30% risk of NEC; however, further study has indicated that it is indomethacin treatment, rather than the PDA itself, that increases the risk of NEC. Subsequent randomized controlled trials and Cochrane reviews have indeed demonstrated an increased rate of NEC in premature infants treated with indomethacin. Furthermore, recent data have found that PDA closure with ibuprofen was as effective as indomethacin and resulted in a greater than 50% risk reduction of NEC (Ohlsson et al., 2015).

More serious forms of CHD (excluding atrial septal defects, PDA, and ventricular septal defects) are associated with an increased incidence of NEC. The Vermont Oxford Network recently reported a 13% risk of NEC in VLBW infants with CHD compared with 9% in VLBW infants without CHD. In addition, the combination of CHD and NEC increased the overall mortality rate to 55% (Fisher et al., 2015).

Blood Transfusions

There is a growing body of evidence that suggests an association between packed red blood cell (PRBC) transfusion and NEC. It is hypothesized that intestinal vascular autoregulation occurs after correction of anemia leading to transfusion-related acute gut injury (or “TRAGI”) (Marin and Strickland, 2013; Nickel and Josephson, 2015). More data are needed to better understand this pattern as all studies to date are retrospective, and there is at least one cohort study showing no temporal association of NEC and PRBC transfusions.

Infectious Agents

Though NEC typically presents sporadically, there are numerous reports of NEC outbreaks in the NICU setting and occasional epidemics that seem to be associated with a single, presumably causative, bacterial pathogen (Boccia et al., 2001). Organisms that have been associated with NEC include *Klebsiella pneumoniae*, *Escherichia coli*, *Clostridium perfringens*, coagulase-negative staphylococci, and rotavirus. Although it has been widely hypothesized that NEC is caused by a single infectious agent, no single pathogen has fulfilled all of Koch postulates, and it is now presumed that abnormal colonization of the premature infant gut with pathogenic bacteria is a key contribution to but not the absolute cause of NEC.

Pathogenesis

The exact mechanism of NEC pathogenesis has long been the scourge of many research laboratories; despite decades of dedicated

research, a complete understanding of NEC pathogenesis remains elusive. The current understanding of the disease is that it is multifactorial, with the combination of impaired intestinal perfusion, abnormal bacterial colonization, impaired gut barrier function, and an immature, overactive immune response leading to intestinal inflammation, ischemia, and eventual necrosis.

Bowel Ischemia

Early hypotheses regarding NEC pathogenesis revolved around the idea that perinatal hypoxemic/ischemic events led to splanchnic hypoperfusion and resultant bowel injury (Touloukian et al., 1972). Supporting this hypothesis, histologic specimens of NEC demonstrate ischemic features such as mucosal ulceration and coagulative necrosis (Nowicki, 2005). Epidemiologic findings, including the increased incidence of NEC in infants with severe CHD, maternal cocaine use, and, potentially, an association with blood transfusion, also support this mechanism. However, the vast majority of infants with NEC have no antecedent hypoxemic event (Stoll et al., 1980). In addition, many NEC animal models use intermittent hypoxia to induce intestinal injury similar to human NEC, though often an additional factor such as a pathologic bacterium or lipopolysaccharide is required to induce NEC, suggesting hypoxia alone is insufficient to cause NEC (Sodhi et al., 2008). More recent evidence would suggest that an exaggerated inflammatory response in the premature intestine leads to alteration of intestinal microcirculatory homeostasis, regulated by a balance between vasodilatory nitric oxide and the vasoconstricting mediator endothelin-1 (Watkins and Besner, 2013). Mucosal inflammation alters the balance to favor vasoconstriction, which leads to intramural microvascular ischemia and represents a critical secondary event in NEC pathogenesis but most likely not the initiating factor.

Abnormal Bacterial Colonization

Compared with full-term neonates, premature neonates have decreased overall bacterial diversity as well as a decreased quantity of commensal organisms such as *Bifidobacteria* species (spp.) and *Lactobacillus* spp. that protect against inflammation and promote intestinal health (Gewolb et al., 1999). In addition, there have been several reports of local NEC outbreaks suggesting that bacteria may play a causative role in NEC pathogenesis (Boccia et al., 2001). Although there have been numerous studies attempting to identify specific bacteria associated with NEC, there is little consensus, and no consistent bacterial species has been identified that meets criteria as a cause of NEC. Even so, germ-free animals do not develop NEC (Museumche et al., 1986), and it is accepted that abnormal colonization of the intestine with potentially pathogenic gram-negative bacteria such as *Escherichia*, *Salmonella*, *Shigella*, *Klebsiella*, and/or *Pseudomonas* plays a key role in NEC pathogenesis (Grishin et al., 2013).

Impaired Gut Barrier Function and Proinflammatory Response

Regardless of the etiology of the initial insult, these events lead to breakdown of the intestinal epithelial barrier coupled with an exaggerated and immature immune response. This, in turn, results in a proinflammatory response that drives the progression of NEC.

The centerpiece of the proinflammatory response appears to be toll-like receptor 4 (TLR4) (Hackam et al., 2013). TLR4 is a

highly conserved pattern-recognition receptor that is activated by lipopolysaccharide, a virulent cell wall protein found on gram-negative bacteria. Full-term infants express low levels of TLR4 on the intestinal mucosa. In contrast, the premature gut is characterized by high levels of TLR4. When the premature gut is colonized with pathogenic, gram-negative bacteria, there is an exaggerated downstream inflammatory response mediated by increased production of nuclear factor kappa B, which drives transcription of proinflammatory cytokines (e.g., interleukin (IL)-1 and tumor necrosis factor- α), inducible nitric oxide synthase, and phospholipase A2 (Gribar et al., 2009). Premature infants have also shown a propensity to synthesize the proinflammatory cytokine IL-8 in response to pathogenic bacteria (Claud et al., 2004). In addition, premature infants have decreased platelet-activating factor (PAF)-acetylhydrolase activity, which predisposes to increased levels of PAF, a potent proinflammatory mediator that contributes to NEC (Caplan et al., 1990). This exaggerated proinflammatory response leads to gut barrier breakdown, further translocation of pathogenic bacteria, systemic sepsis, and continued overactivation of the proinflammatory cascade.

In addition to the enhanced proinflammatory pathways, antiinflammatory mediators such as epidermal growth factor (EGF) are depleted in premature neonates (Shin et al., 2000). In particular, heparin-binding EGF (HB-EGF), a member of the EGF family, is a growth factor that functions to maintain gut barrier function and facilitates intestinal epithelial repair following injury. HB-EGF also functions as a potent antiinflammatory mediator and has shown benefit in animal models as a treatment for intestinal injury and prevention of NEC. Furthermore, HB-EGF is present in breast milk and is decreased in infants with NEC, suggesting a significant role in NEC pathogenesis (Besner, 2015).

This combination of an overzealous proinflammatory response without counterregulation by key antiinflammatory mediators, coupled with impairment of intestinal epithelial barrier, results in

severe intestinal inflammation and necrosis, the clinical hallmarks of NEC.

Clinical Presentation

The clinical presentation of NEC can include a wide range of findings. In mild cases, the only signs may include slight hematochezia and high gastric residuals. More involved cases of NEC may present with abdominal distention and tenderness with frank intolerance of feedings. In the most severe cases, signs of significant inflammatory response and sepsis are present, which may include thrombocytopenia, leukopenia, lethargy, acidosis, hypotension, apnea, and death. Additionally, the time course for progression from first symptoms to significant hemodynamic compromise can be extremely variable, with the potential for rapid progression and arrest if unrecognized.

A common finding with new onset NEC is pneumatosis intestinalis (Fig. 76.1) on abdominal radiograph, and this can be seen with or without the presence of portal venous gas (Fig. 76.2). The **Bell criteria**, published first in 1978 (Bell et al., 1978) and then further modified in 1986 (Walsh and Kliegman, 1986), is a classification system that was developed with the goal of standardizing the therapeutic options for NEC based on the precise stage of the disease at diagnosis (Table 76.1). The presence of portal venous gas with or without pneumatosis intestinalis is associated with a worse prognosis (Molik et al., 2001). Although it has been debated whether the presence of portal venous gas on abdominal radiograph is a relative indication for an operation, it is widely regarded as an indicator of poor clinical outcome. It is important to obtain multiple view abdominal films in order to identify the presence of pneumoperitoneum, and this is most easily identified on a cross-table lateral or right lateral decubitus film (Fig. 76.3A). Other more occult findings of free air that may be seen include a periumbilical collection or so-called “football sign,” seen on an

• **Fig. 76.1** (A) Typical abdominal radiographic appearance of intestinal pneumatosis seen in necrotizing enterocolitis: dark concentric rings around the bowel loops in the right upper quadrant. (B) Radiograph displaying the *bubbly gas* pattern occasionally seen in necrotizing enterocolitis. (Courtesy Dr. Lalo Cabrera-Meza, Baylor College of Medicine, Houston, Texas.)

anterior–posterior film (see Fig. 76.3B). More recently, ultrasonographic findings of portal venous gas and pneumatosis have been used to diagnose NEC. Bohnhorst et al. (2003) and Dördelmann et al. (2009) have shown that these sonographic findings may allow for earlier, more precise diagnosis of NEC. Ultrasound finding of portal venous gas, however, should be used with caution when deciding on the need for operative intervention, as this is found in up to 10% of patients with mild cases of NEC that resolve with medical management alone (Silva et al., 2007; Garbi-Goutel et al., 2014).

Despite the development of scoring systems, it is still difficult to predict which infants will progress rapidly to fulminant NEC requiring operative intervention and which will have a more benign clinical course. Importantly, some infants who require surgery will remain stable enough to transport to the operating room for surgery while others will progress so rapidly that transport to the operating room for intervention is unsafe, requiring operative intervention in the NICU or resulting in the infant succumbing to his or her disease. Ng et al. (2013) described the LIT score, using a combination of biomarkers to attempt to identify the most severely affected surgical NEC patients. A combination of gut barrier biomarkers, *L-FABP*, *I-FABP*, and *7FF3* (LIT), was measured, and infants who went on to develop surgical NEC had significantly higher levels of biomarkers when compared with infants who only exhibited signs of septicemia or medical NEC. Although this study has shown promise in identifying the most high-risk patients, it is currently not used at most centers.

TABLE 76.1

Modified Bell Staging Criteria for Necrotizing Enterocolitis

| Stage | Systemic Signs | Intestinal Signs | Radiologic Signs | Treatment |
|-----------------------------------|---|---|--|--|
| I: Suspected | | | | |
| A | Temperature instability, apnea, bradycardia | Elevated pregavage residuals, mild abdominal distention, occult blood in stool | Normal or mild ileus | NPO antibiotics × 3 days |
| B | Same as for IA | Same as for IA, plus gross blood in stool | Same as for IA | Same as for IA |
| II: Definite | | | | |
| A: Mildly ill | Same as for IA | Same as for I, plus absent bowel sounds, abdominal tenderness | Ileus, intestinal pneumatosis | NPO, antibiotics × 7–10 days |
| B: Moderately ill | Same as for I, plus mild metabolic acidosis, mild thrombocytopenia | Same as for I, plus absent bowel sounds, definite abdominal tenderness, abdominal cellulitis, right lower quadrant mass | Same as for IIA, plus portal vein gas, with or without ascites | NPO, antibiotics × 14 days |
| III: Advanced | | | | |
| A: Severely ill, bowel intact | Same as for IIB, plus hypotension, bradycardia, respiratory acidosis, metabolic acidosis, disseminated intravascular coagulation, neutropenia | Same as for I and II, plus signs of generalized peritonitis, marked tenderness, and distention of abdomen | Same as for IIB, plus definite ascites | NPO, antibiotics × 14 days, fluid resuscitation, inotropic support, ventilator therapy, paracentesis |
| B: Severely ill, bowel perforated | Same as for IIIA | Same as for IIIA | Same as for IIB, plus pneumoperitoneum | Same as for IIA, plus surgery |

Treatment

Medical Management

Treatment for NEC is generally geared toward supportive care, since no particular therapy or intervention has been identified to slow or stop the progression of this disease process. Prompt initiation of broad-spectrum antibiotics, cessation of feedings, and gastric decompression are the keys to treatment. There is no data-driven consensus on the specific antibiotic regimen for treating NEC, as highlighted by an international survey and Cochrane review ([Shah and Sinn, 2012](#); [Zani et al., 2015](#)). Therefore antibiotics are often prescribed by institutional protocol depending on local antibiotic sensitivities. In general, broad-spectrum antibiotics are initiated early to cover typical enteric flora, including gram-negative and anaerobic coverage. In centers with frequent staphylococcal colonization, vancomycin should also be considered. Conservative treatment in this fashion is usually continued for a minimum of 7 to 10 days depending on the severity of clinical and radiographic findings, although no studies have specifically investigated the optimal course for antibiotic therapy. In patients who require surgical intervention, intraoperative cultures may help guide antibiotic therapy.

Generally, as long as the clinical status of the patient is stable or improving with these measures, intermittent radiographs monitoring pneumatosis and medical management are continued until resolution of the pneumatosis on films and improvement in the abdominal examination. Any deviation from a stable clinical course exhibited by hemodynamic instability, respiratory compromise from abdominal distention, thrombocytopenia, anemia, or disseminated intravascular coagulation may obligate surgical intervention. Once the antibiotic course has been completed and

the abdominal examination normalized, enteral feeds are slowly introduced and advanced carefully.

Surgical Management

Despite optimal neonatal intensive care, up to 50% of infants with NEC will require surgical intervention. The one truly absolute indication for operative intervention is pneumoperitoneum. Relative indications include diffuse pneumatosis intestinalis, portal venous gas, a fixed, dilated loop of intestine, or clinical deterioration despite maximal medical therapy. When the severity of NEC reaches the point of surgical intervention, there is an associated increase in mortality: 35% for VLBW infants with surgical NEC compared with 21% for VLBW infants with medical NEC ([Fitzgibbons et al., 2009](#)). In addition, surgical NEC survivors are at increased risk for SBS, intestinal strictures ([Heida et al., 2015](#)), and NDI compared with infants with medical NEC ([Murthy et al., 2014](#)).

Laparotomy Versus Peritoneal Drain Placement

Historically, surgical intervention for NEC was predicated on exploratory laparotomy, resection of all segments of necrotic bowel, and creation of enterostomies ([Walsh and Kliegman, 1986](#)). More recently, however, there has been a movement toward use of primary peritoneal drainage (PPD) as a definitive therapy for NEC. PPD was first used as a temporizing measure in 1977 ([Ein et al., 1977](#)) and was described as definitive therapy in 1992 ([Takamatsu et al., 1992](#)). Since that time there have been many studies comparing the effectiveness of PPD with laparotomy. In 2001, a metaanalysis was unable to determine a difference in outcomes between PPD and laparotomy in infants with NEC who required surgical

intervention (Moss et al., 2001). This was followed by an observational study using the National Institute of Child Health and Human Development database that also found no difference in mortality between PPD and laparotomy for extremely low birth weight (ELBW) infants with surgical NEC (Blakely et al., 2006). However, this study also showed a trend toward improved neurodevelopmental outcomes in the laparotomy group. In contrast, a study using the Kids' Inpatient Database found that PPD was associated with a 5.7-fold increased odds of death compared with laparotomy; this has been confirmed in additional cohort studies (Choo et al., 2011). All of these studies are confounded by selection bias, with the most critically ill and most premature infants tending to be treated with PPD.

These conflicting data led to two randomized controlled trials that compared PPD and laparotomy, the NEC Steps and NET trials. The NEC Steps trial found that in VLBW infants there was no statistical difference in 90-day mortality or duration of parenteral nutrition between PPD as definitive therapy and laparotomy (Moss et al., 2006). The NET trial studied PPD as a temporizing measure versus initial laparotomy in ELBW infants and also found no difference in mortality between the two groups. There was, however, a trend toward prolonged time to full enteral feeds in the PPD group (Rees et al., 2008). Of note, 50% of infants in the PPD groups required eventual laparotomy in both trials. Unfortunately, both of these studies were underpowered and did not look at NDI as an outcome. As a result, both a Cochrane review (Rao et al., 2011) and a recent systematic review by the American Pediatric Surgical Association outcomes committee (Downard et al., 2012) have concluded that there is still insufficient evidence to recommend PPD as a definitive therapy for surgical NEC. We will hopefully have an answer to this debate after the completion of the NEST trial (NCT 01029353), which has randomized infants weighing less than 1000 g to either PPD or laparotomy and will assess outcomes, including NDI, at 18 to 22 months.

Surgical Options

It is important to know that several surgical options exist when the decision is made to perform a laparotomy for NEC. The traditional approach of resection of necrotic bowel and ostomy creation is effective but carries the risks of stoma complications as well as the need for a second operation for ostomy takedown (O'Connor and Sawin, 1998). Resection with primary anastomosis in an appropriately sized and hemodynamically stable premature infant avoids the risks of stomas and has the advantage of requiring only one operation (Griffiths et al., 1989). However, the risk of leak and stricture may be greater with this treatment, and more data are needed before a definitive recommendation for primary anastomosis can be made.

For patients with more extensive necrosis or multiple segments of compromised bowel, additional surgical options such as the "clip and drop" technique (Vaughan et al., 1996) or the "patch, drain, and wait" approach (Moore, 2000) require multiple, staged operations but may result in improved preservation of bowel length in those infants at high risk of developing SBS. Data for these techniques are limited to small case series in the surgical literature.

Outcomes

NEC-associated mortality remains high, with the poorest prognosis in VLBW infants who develop surgical NEC. Overall, the mortality for VLBW infants with medical NEC is 21%, ranging between

6% in infants weighing 1500 g to nearly 50% in infants less than 500 g. Similarly, infants with NEC who weigh less than 500 g and require surgical intervention have an associated mortality of nearly 50%. Unlike medical NEC, mortality in surgical NEC remains at 30%, even for infants weighing 1500 g (Fitzgibbons et al., 2009).

One of the most common delayed complications in survivors of both medical and surgical NEC is the formation of intestinal strictures, leading to feeding intolerance. Strictures occur in up to 35% of NEC survivors after recovery and reinitiation of enteral feeds (Horwitz et al., 1995). Although the typical presentation is feeding intolerance 2 to 3 weeks after reinitiation of feeds, NEC-associated strictures have been reported as late as 6 weeks following a course of NEC (Valla et al., 1985). Most strictures associated with NEC will require surgical intervention and are diagnosed using fluoroscopic imaging studies.

Other complications associated with NEC include SBS, line infections from chronic central venous access, and parenteral nutrition-associated liver disease (PNALD). Premature infants are at increased risk for PNALD in general, and therefore PNALD is frequently observed in infants who suffer from NEC. Additionally, recurrent NEC occurs in up to 6% of patients, with medical management being successful for most recurrent cases (Stringer et al., 1993).

Long-term NDI is common in survivors of surgical NEC. Previous studies have demonstrated NDI in up to 50% of NEC survivors at 12 to 20 months of age (Sonntag et al., 2000). A study using the NICHD database found that ELBW infants with surgical, but not medical, NEC had significantly increased odds of NDI compared with infants without NEC (Hintz et al., 2005).

Prevention

Because of the acute presentation of NEC, its rapid progression, and the lack of readily available screening tests, the most promising method of reducing NEC morbidity and mortality lies with prevention. Furthermore, preventative measures are desperately needed as improved neonatal care has resulted in the increased survival of extremely premature infants, who are at the highest risk for developing NEC. In animal studies, a lower incidence of NEC has been associated with breast-milk feeding (Dvorak et al., 2004), supplementation with immunoglobulin A (IgA) (Barlow et al., 1974), probiotics (Caplan et al., 1999), PAF antagonists (Caplan et al., 1997), polyunsaturated fatty acids (PUFAs) (Lu et al., 2007), EGF (Dvorak et al., 2008), intestinal alkaline phosphatase (Whitehouse et al., 2010), or oxygen radical scavengers (Cueva and Hsueh, 1988). Human studies have shown limited success in the prevention of NEC by using IgA (Eibl et al., 1988), steroids (Halac et al., 1990), PUFAs (Carlson et al., 1998), glutamine (El-Shimi et al., 2015), arginine (Mitchell et al., 2014), and lactoferrin (Manzoni et al., 2014). To date, none of these strategies have shown a significant reduction in the incidence of NEC in large-scale randomized trials, and limited evidence exists to argue for widespread implementation. Current evidence suggests that the two most promising strategies for NEC prevention are exclusive use of human milk and probiotic supplementation.

Exclusive Use of Human Milk

Human milk is the ideal nutritional source for the preterm infant for a myriad of reasons. Importantly for NEC prevention, human milk provides an array of antiinfectious factors such as IgA and

probiotics, as well as essential nutrients that promote intestinal health. There are now numerous randomized controlled trials that have demonstrated a decreased incidence of NEC when premature infants are fed exclusively with human milk, when compared with formula feeding (Schanler et al., 2005; Sullivan et al., 2010; Cristofalo et al., 2013). In addition, there is now a growing body of evidence, including results from a recent randomized controlled trial, of a decreased incidence of NEC in premature infants fed exclusively with donor breast milk, when compared with formula feeding (Cristofalo et al., 2013). Recent Cochrane reviews have concluded that there is compelling evidence to suggest that all premature infants should be fed with human milk when available (Quigley and McGuire, 2014). Future studies will need to evaluate the risk of NEC in babies fed human milk fortified with formula, as this is frequently used for VLBW infants, with that of feeding with standard human milk or formula alone.

In addition to the practice of using human milk, many have posited that carefully regimented feeding regimens may decrease the incidence of NEC. Despite the theoretical benefits, several randomized controlled trials and two recent Cochrane reviews have found no difference in NEC incidence with fast versus slow feeding advancement (Morgan et al., 2015), delayed versus early initiation of enteral feeds (Morgan et al., 2014), and continuous versus bolus enteral feeding (Downard et al., 2012).

Probiotics

Another promising method to prevent NEC is supplementation with probiotics. As discussed earlier, there is abnormal colonization of the premature infant's intestine, and supplementation with commensal, nonpathologic probiotics may blunt the proinflammatory response that drives NEC. Indeed, there are several randomized controlled trials showing a decrease in NEC incidence in VLBW infants after supplementation with probiotics (Wang et al., 2012). In fact, a recent Cochrane review concluded that probiotic supplementation in premature infants is associated with a decrease in both overall mortality and incidence of NEC (Alfaleh and Anabrees, 2014). This group has updated its stance to "strongly encourage" a change in practice to provide routine supplementation with probiotics in the premature infant population. One issue that must still be addressed, however, is the type, timing, and length of treatment, as many of the trials have used different probiotic regimens. In addition, care must be taken when choosing probiotic formulas as these preparations are not carefully regulated, and there have been reports of increased asthma in childhood related to probiotics (Kalliomäki et al., 2007) as well as adverse outcomes in critically ill adults with pancreatitis who were treated with probiotics (Besselink et al., 2008). However, to date, the overwhelming body of evidence suggests that probiotics are safe and effective in preventing NEC.

Short Bowel Syndrome

Intestinal failure is defined as the inability of the intestine to meet energy, fluid, and electrolyte requirements because of inadequate length or function. SBS is the most common form of intestinal failure in children. Frequent etiologies of pediatric SBS include NEC, gastroschisis, intestinal atresia, and midgut volvulus. In this way, SBS in children is often the result of massive intestinal resection in young infants.

The management of children with SBS requires complex and multidisciplinary care. Recently, select tertiary pediatric institutions

have implemented dedicated intestinal rehabilitation programs that incorporate a multidisciplinary team of providers to facilitate long-term care of intestinal failure. Data have demonstrated a survival benefit when children with SBS are treated at dedicated, multidisciplinary pediatric intestinal rehabilitation centers (Modi et al., 2008).

The goal of intestinal rehabilitation is to slowly advance enteral feeds and wean parenteral nutrition as the remaining bowel undergoes the process of intestinal adaptation. Following massive intestinal resection, it is well established that the remnant bowel undergoes significant structural alterations. From a macroscopic standpoint, the proximal bowel dilates to increase the mucosal surface area for nutrient absorption. Any increase in bowel length beyond the overall growth of the patient is negligible with the exception of the extremely preterm infant in whom the bowel may continue to lengthen until term. A recent study, using intraoperative bowel length measurements, demonstrated that small bowel length can double, when the extremely premature neonate is compared with a full-term young infant (Struijs et al., 2009). Microscopic changes in intestinal adaptation include increased crypt depth, greater villous height, and an increased enterocyte number to allow for mucosal hyperplasia. The process of intestinal adaptation likely begins soon after resection but may continue for years in children (Squires et al., 2012). It is thought that the ileum adapts better than the jejunum, and this may explain why patients with an intact ileocecal valve have a better chance of weaning from parenteral nutrition (Khan et al., 2015).

Over the past decade, significant improvement has been observed in the long-term survival of children with SBS. The improved outcomes are likely multifactorial and related to multidisciplinary care, safer delivery of parenteral nutrition, improved prevention and treatment of central line-associated sepsis, and innovative bowel lengthening techniques. Long-term survival of children with SBS now routinely reaches 80%–90% in dedicated intestinal failure centers (Javid et al., 2010; Khalil et al., 2012; Infantino et al., 2013). It is now a reasonable expectation that, if children survive their neonatal critical illness and barring severe extraintestinal comorbidities, children with intestinal failure can survive to school age and beyond. Even children with the shortest bowel lengths can have reasonable long-term outcomes, although they require ongoing advanced care (Infantino et al., 2013; Sanchez et al., 2013). In addition, preliminary studies on the neurodevelopment of children with intestinal failure have shown encouraging results (Javid et al., 2015). Controversy exists as to the minimum length of small bowel required for survival, and this issue poses both physiologic and ethical challenges. Infants with any length of remaining viable bowel distal to the ligament of Treitz have shown reasonable survival in contemporary series, although infants with the shortest bowel remnants may ultimately require intestinal transplantation as older children.

In particular, modification of intravenous lipid in infants and toddlers with intestinal failure has led to a dramatic reduction in the incidence and severity of parenteral nutrition-associated cholestatic liver disease, now more appropriately termed *intestinal failure–associated liver disease (IFALD)*. While the etiology of IFALD is not fully understood, it has been demonstrated that replacement of the standard soybean-based lipid emulsion in parenteral nutrition with fish oil–based lipids rich in omega-3 can lead to biochemical reversal of IFALD (Puder et al., 2009). In addition, emerging data have shown that restriction of intravenous soy-based lipid to a total allotment of 1 g/kg per day can both prevent and reverse IFALD in infants with SBS (Rollins et al., 2013; Sanchez et al.,

2013). Many centers now routinely treat infants at risk for IFALD with lipid restriction to avoid the complications of IFALD. The reduction in the incidence of IFALD has allowed providers to focus on long-term intestinal rehabilitation in these patients rather than strive for early intestinal and liver transplantation.

The Pediatric Intestinal Failure Consortium (PIFCon) was established in 2006 and consists of 18 institutions throughout North America with multidisciplinary pediatric intestinal rehabilitation programs. In a multicenter retrospective cohort study of patients treated between 2000 and 2007 at PIFCon centers, 27% of patients died, and 26% underwent intestinal transplantation (Squires et al., 2012). Nearly one-half of patients enrolled in the retrospective study attained enteral autonomy. Interestingly, children continued to wean off parenteral nutrition several years after referral to an intestinal rehabilitation center indicating that the process of intestinal adaptation in children may take years. Additional data from the PIFCon database demonstrate that infants who suffered from NEC had a greater chance of reaching enteral autonomy than children with alternative etiologies of SBS (Khan et al., 2015).

The role of surgical bowel lengthening in the management of pediatric SBS continues to evolve. Common techniques for bowel lengthening include the longitudinal intestinal lengthening and tapering procedure designed by Bianchi (Bianchi, 1999) and the serial transverse enteroplasty (STEP) introduced in 2002 (Kim et al., 2003). Both procedures are designed to prolong intestinal transit time so that nutrient absorption can be optimized. Children with short bowel anatomy who plateau in their enteral feeding advancement and develop significant bowel dilation are the ideal candidates for a bowel lengthening procedure. Outcomes from lengthening procedure vary by center, although a recent publication from the International STEP Data Registry reported that 55% of children reached enteral autonomy after STEP (Jones et al., 2013).

Intestinal transplantation remains an option for children with severe SBS who cannot attain enteral autonomy over time. Most centers also consider loss of the majority of central venous access sites because of thrombosis as an indication for transplantation. With the recent success of intestinal rehabilitation, however, the utilization of intestinal transplantation in young children with

SBS has decreased. Long-term patient and graft survival in pediatric intestinal transplantation are improving and approaching the outcomes seen in liver and kidney transplantation (Sudan et al., 2014).

Disorders of the Liver

ERIN R. LANE, KAREN M. CHISHOLM, AND KAREN F. MURRAY

KEY POINTS

- Early onset (<24 hours of age) or new jaundice is never normal and should be investigated.
- Initial evaluation of a jaundiced infant should always include conjugated and unconjugated bilirubin levels.
- Infants presenting with jaundice secondary to conjugated hyperbilirubinemia should undergo expedient evaluation for potentially life-threatening and treatable causes of cholestasis and then for other causes.

Introduction to Neonatal Liver Disease

The liver is the largest abdominal organ and serves as the body's main location of energy production, metabolism, protein synthesis, and detoxification. Embryologically, the liver is derived from an endodermal outgrowth from the foregut and septum transversum. There are multiple cell types within the liver parenchyma, including hepatocytes, cholangiocytes, stellate cells, endothelial cells, and cells of the innate immune system. The key roles of the hepatocyte include protein synthesis, fatty acid synthesis and oxidation, formation of lipids, cholesterol and bile salts, bilirubin metabolism, gluconeogenesis, glycogen synthesis, urea cycle and production of ammonia, and detoxification. The hepatocyte is the only cell in the body that manufactures albumin, fibrinogen, and prothrombin clotting factors. In the setting of significant liver injury, loss of normal hepatocyte synthetic function often results in the development of coagulopathy and hypoalbuminemia.

Bile is primarily composed of bile acids, bilirubin, and fats, which are manufactured in the hepatocyte, secreted into the canaliculus, transported into the biliary ducts, and, ultimately, secreted into the intestine or stored within the gallbladder. Bile is critical for solubilizing dietary fats and fat-soluble vitamins (A, D, E, and K) to make them available for absorption. Disruption of this process at any level results in cholestasis. Cholestasis refers to obstruction of the normal excretion of bile from the liver resulting in the abnormal accumulation of bile components within the liver and serum. While cholestasis is not synonymous with jaundice from conjugated hyperbilirubinemia, serum conjugated bilirubin level is the most clinically useful marker of cholestasis.

Like the lungs, the liver is unique in that it has a dual blood supply: nutrient-rich venous blood from the portal vein and oxygen-rich arterial blood from the hepatic artery. Venous drainage of the liver occurs through the hepatic veins. In the fetus, the

umbilical vein delivers oxygenated blood to the liver via the left portal vein and the ductus venosus, which then joins the left hepatic vein as it drains into the inferior vena cava. The ductus venosus closes spontaneously at birth. Congenital anomalies of the portal vein or thrombosis associated with umbilical vein catheter placement may lead to portal vein obstruction and portal hypertension. Portal hypertension describes a pathologic increase in venous pressure in the portal venous system and occurs when the portal pressure rises above 10 mmHg. Portal hypertension may be pre-hepatic (portal vein), intrahepatic (cirrhosis), or posthepatic (hepatic venous) in etiology. Signs and symptoms of portal hypertension include splenomegaly, ascites, and gastrointestinal bleeding secondary to bleeding varices.

Neonates with liver disease may present with an array of clinical phenotypes ranging from asymptomatic jaundice to acute liver failure. Clinical evaluation and management differ depending on underlying etiology. Clinical signs suggestive of underlying liver disease include ascites, hepatomegaly with or without splenomegaly, coagulopathy, elevated transaminases, hyperammonemia, hypoglycemia, and cholestasis. The initial evaluation of suspected liver disease must include a careful physical examination, laboratory evaluation, and imaging. The initial laboratory evaluation for suspected liver disease comprises an assessment of hepatocellular injury and function, including aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase (ALP), gamma-glutamyl transpeptidase (GGT), conjugated and unconjugated bilirubin levels, prothrombin time/international normalized ratio (INR), and albumin levels. Elevations in serum ALT and AST indicate hepatocellular injury; however, they are not specific to the liver and may be found in other tissues such as red blood cells and skeletal muscle. An elevation in ALP and GGT may indicate biliary obstruction or inflammation; however, care must be taken in children, as elevated ALP is also indicative of normal bone growth and metabolism. As stated previously, an elevation in transaminases (AST, ALT) indicates hepatocyte injury, whereas an elevation in prothrombin time/INR and hypoalbuminemia indicates a loss of normal hepatocyte function and most likely a greater degree of hepatocyte injury. The most appropriate initial imaging modality is abdominal ultrasound (US), which can detect anatomic or vascular anomalies, thrombosis, or suggest underlying portal hypertension.

Liver disease in the neonate frequently presents with new or persistent jaundice. Infants presenting with new jaundice deserve an urgent evaluation, as this is never normal. Term infants with jaundice persisting beyond 14 days or preterm infants with jaundice

beyond 21 days of life deserve expedient evaluation (Fawaz et al., 2017; Murray, Horslen, 2014). In any jaundiced infant, it is necessary to determine whether jaundice is due to conjugated versus unconjugated hyperbilirubinemia. Although the differential of potential causes will vary by the type of predominant bilirubin, prioritizing the evaluation to identify those conditions where early intervention is associated with improved outcome, such as sepsis, is prudent.

Elevated unconjugated hyperbilirubinemia is often seen secondary to breast milk jaundice, sepsis, hemolysis secondary to blood group incompatibility (ABO and rhesus) or red blood cell dyscrasia, and, more rarely, Crigler–Najjar syndrome. While physiologic jaundice and breast milk jaundice are common, jaundice secondary to unconjugated hyperbilirubinemia should still be investigated if it is of very early onset (within 24 hours of life), prolonged beyond 14 days, or at high levels. Breast milk jaundice is the most likely etiology of unconjugated hyperbilirubinemia if the serum level is downtrending; there is no evidence of hemolysis, infection, abnormal thyroid function, or elevated serum aminotransferases; and the child is clinically well. However, if unconjugated hyperbilirubinemia persists or is rising, or the child is ill, disorders influencing bilirubin conjugation and hemoglobin metabolism should be investigated.

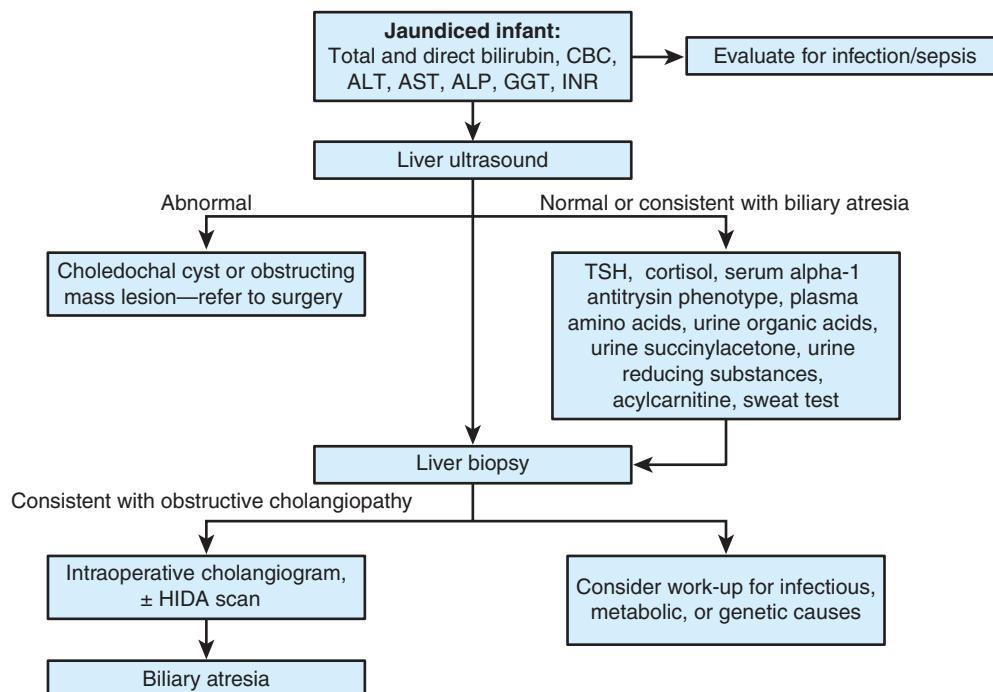

The presence of conjugated hyperbilirubinemia (defined as conjugated bilirubin level $\geq 15\%$ of the total) should raise concern for underlying liver disease. An initial approach to the evaluation of neonatal conjugated hyperbilirubinemia is shown in Fig. 77.1. Specific etiologies of neonatal cholestasis are reviewed below and summarized in Table 77.1. Idiopathic neonatal hepatitis is a term historically applied to infants presenting with neonatal cholestasis or hepatitis in whom no specific etiology could be identified. Liver biopsies in these infants often demonstrate nonspecific intrahepatic cholestasis and giant cell transformation of hepatocytes (Balistreri,

Bezerra, 2006) (Fig. 77.2). Currently, it is recognized that multinucleated giant cells represent a stereotypical response by the immature liver to many etiologies of hepatocellular injury, including infection, biliary obstruction, and metabolic disease. Today, with advancements in next generation DNA sequencing, the number of identifiable etiologies of neonatal cholestasis and hepatitis has increased dramatically, further reducing the frequency and utility of this diagnosis.

Cholestatic Liver Disease

Cholestasis refers to obstruction of the normal excretion of bile from the liver, resulting in abnormal accumulation of bile salts, bilirubin, and lipids in the blood. In infants, cholestasis may present as asymptomatic jaundice, pruritus, unexplained fat-soluble-vitamin deficiency, or acute liver failure. The presence of acholic stools suggests functional or anatomic biliary obstruction. The following sections review the most common etiologies of neonatal cholestasis and discuss the corresponding disease-specific evaluation and clinical management.

Nutritional management is critical and central to the care of infants with chronic cholestasis. Growth failure commonly occurs in time, secondary to malabsorption from inadequate bile flow, intestinal congestion from portal hypertension, and increased caloric needs in the setting of chronic liver inflammation. The estimated daily caloric intake for infants with chronic cholestasis may approach 150% of that of healthy infants (Hsu, Chang, 2014). Additionally, malabsorption of fat-soluble vitamins (A, D, E, and K) can result in progressive coagulopathy and pathologic fractures. While enteral nutrition is preferable, some infants go on to require nutritional optimization with total parenteral nutrition. The general principles of nutritional management in cholestatic infants include assurance

• **Fig. 77.1** Algorithmic approach to the evaluation of an infant with conjugated hyperbilirubinemia. ALP, Alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; CBC, complete blood count; GGT, gamma-glutamyl transpeptidase; HIDA, hepatobiliary iminodiacetic acid scan; INR, international normalized ratio; TSH, thyroid-stimulating hormone.

TABLE 77.1 Causes of Neonatal Cholestasis

| | |
|--------------------------|--|
| Infection | Herpes simplex virus Cytomegalovirus Adenovirus Hepatitis B Sepsis/urinary tract infection Cholecystitis Cholangitis |
| Endocrine | Hypothyroidism Panhypopituitarism Adrenal insufficiency |
| Metabolic/Genetic | Galactosemia Tyrosinemia type 1 Dubin–Johnson syndrome Rotor syndrome Bile acid synthesis defects α -1 Antitrypsin deficiency Cystic fibrosis Defects of bile transport (progressive familial intrahepatic cholestasis) Peroxisome biogenesis disorders |
| Cardiovascular | Heart failure Shock Hepatic ischemia |
| Syndromic | Trisomy 21 Trisomy 13 Trisomy 18 Joubert syndrome Ivemark syndrome Beckwith–Wiedemann syndrome Bardet–Biedl syndrome |
| Biliary | Biliary atresia Choledochal cyst Alagille syndrome Choledocholithiasis Neonatal sclerosing cholangitis Caroli disease Obstruction from mass or stricture |
| Nutritional | Total parenteral nutrition |

of adequate absorbable calories and nutrients, monitoring levels of and supplementation with fat-soluble vitamins, and preparation to escalate the nutritional support and supplementation in infants who cannot sustain adequate intake for growth orally, with supplemental enteral feeds via nasogastric tube or initiation of parenteral nutrition in situations of failure to grow or gain weight adequately with maximal enteral nutrition. The selection of formula should consider medium-chain triglyceride (MCT) content, as this fat source is directly absorbed into the portal venous system and does not require emulsification by bile acids or active transport that is

disrupted in cholestasis. Children with portal hypertension and ascites also benefit from sodium restriction.

Biliary Atresia

Biliary atresia (BA) is an idiopathic hepatobiliary disorder of infancy characterized by inflammation and progressive fibrosis resulting in the obliteration of the extrahepatic biliary ducts (Balistreri et al., 1996; Hartley et al., 2009). As the disease progresses, the end result is variable destruction and obliteration of the intrahepatic bile ducts. BA is the most common cause of infantile chronic liver disease and most frequent indication for liver transplantation in the pediatric population. The reported incidence of BA is 0.5 to 3.2 per 10,000 live births but varies based on geography and ethnicity. Babies with BA generally present between 2 and 5 weeks of age, but without rapid intervention the natural history of BA is uniform fatality by 2 years of age.

BA is characterized by the anatomy of extrahepatic biliary obstruction (Karrer et al., 1990). Two clinical phenotypes exist: “classical” BA, which is not associated with extrahepatic congenital anomalies, and “BA with splenic malformation,” which presents with other congenital anomalies such as situs inversus, polysplenia or asplenia, vascular and cardiac malformations, and intestinal malrotation.

BA typically presents with cholestatic jaundice and hepato-splenomegaly between 2 and 5 weeks of age. Acholic stools suggest biliary obstruction and are frequently present, but onset is commonly well after the onset of jaundice. If the infant also had a preceding history of physiologic jaundice, the cholestatic jaundice may not be recognized as new; this highlights the importance of evaluating any prolonged or new jaundice in infants. Although splenomegaly is commonly present at diagnosis, other signs of portal hypertension such as ascites generally occur later in the course of disease. As chronic inflammation and cholestasis lead to malabsorption, many infants with BA present with inadequate weight gain.

Expedient differentiation of BA from other causes of neonatal cholestasis is critical, as surgical intervention before 2 months of age has been shown to improve surgical success and outcome (Ohi, 2001; Shneider et al., 2006). If early laboratory evaluations are suggestive of BA, consultation with a pediatric hepatologist is mandatory. Laboratory evaluation early in the course of disease typically demonstrates conjugated hyperbilirubinemia between 2 and 7 mg/dL and total bilirubin levels between 5 and 12 mg/dL (Hsu, Chang, 2014). Elevations in ALT, ALP, and GGT are generally seen (Hsu, Chang, 2014). Abdominal US is recommended as the first-line imaging modality and may demonstrate absence of the gallbladder after adequate fasting or a fibrotic remnant of extrahepatic bile duct. In the porta hepatis a triangular or tubular echogenic cord of fibrous tissue representing the biliary remnant may be described as “triangular cord sign.” The reported sensitivity of this sonographic finding is 73% (Lee et al., 2003). As a follow-up to abdominal US, hepatobiliary scintigraphy with technetium-labeled iminodiacetic acid derivatives (HIDA scan) may be used to assist in the differentiation between obstructive and nonobstructive causes of neonatal cholestasis. In BA, radionuclide scans demonstrate rapid uptake of tracer but absence of excretion into the bowel at 24 hours. The sensitivity of the HIDA scans may be increased by pretreatment with oral phenobarbital (5 mg/kg per day) for 5 days. Care must be taken, however, to not delay definitive diagnosis by awaiting scan results and recognition that functional causes of cholestasis (such as hypothyroidism) can also result in a nonexcreting HIDA scan. Percutaneous liver biopsy is helpful in excluding

• **Fig. 77.2** Neonatal Hepatitis Histology. (A) Low power of a hematoxylin and eosin stain from a liver biopsy demonstrating hepatocytes with giant cell transformation and ballooning. Some cholestasis is evident. (B) Higher power of same biopsy shows the hepatocytes with giant cell transformation as well as a focus of extramedullary hematopoiesis.

• **Fig. 77.3** Biliary Atresia Histology. (A) Hematoxylin and eosin stain of a liver biopsy from a 3-month-old girl demonstrating a proliferation of bile ductules. Bile plugs are present. (B) Masson trichrome stain from a liver transplant specimen from the same girl at 8 months of age. This specimen has diffuse cirrhosis with fibrous expansion of portal tracts. The portal triads lack bile ducts, but there is a marked bile ductule reaction, many containing bile plugs.

alternate causes of cholestasis. Histopathologic findings supportive of a diagnosis of BA demonstrate bile ductular proliferation and bile duct plugging (Fig. 77.3). Given the progressive nature of BA, the histologic findings will vary with the point in progression.

Failure to exclude BA after the above evaluation is complete necessitates surgical exploration with intraoperative cholangiogram. The diagnosis of BA may be made or confirmed at the time of laparotomy with the observation of an atretic biliary tree and intraoperative cholangiogram demonstrating lack of patency in the biliary ductal system. If BA is confirmed, surgical intervention with a Kasai hepatic portoenterostomy is recommended. The Kasai is a surgical procedure that works to restore the normal flow of bile by excising the obstructed bile ducts and creating an anastomosis of a jejunal limb of a Roux-en-Y with the liver at the porta hepatis, the area of the liver from which the bile ducts become extrahepatic. Restoration of bile flow may prevent or delay progression of disease,

worsening of fibrosis, and development of end-stage liver disease. However, despite Kasai portoenterostomy, the majority of children progress to cirrhosis and portal hypertension and ultimately require liver transplantation.

Alagille Syndrome (Arteriohepatic Dysplasia)

Alagille syndrome (ALGS) is an autosomal dominant or sporadic de novo genetic disorder characterized by chronic, progressive cholestasis secondary to a paucity of intralobular bile ducts. The estimated prevalence is 1 in 30,000 live births (Murray and Horslen, 2014). The majority of children with ALGS carry a mutation in the gene *JAG1*, located on chromosome 20 (Li et al., 1997; Oda et al., 1997; Warthen et al., 2006). The product of *JAG1* is a ligand in the Notch signaling pathway that plays a key role in embryogenesis and the pathogenesis of the disorder. A small number of infants

with ALGS have mutations in *NOTCH2* (McDaniell et al., 2006; Kamath et al., 2012).

ALGS is a multisystem syndrome characterized by cholestatic liver disease, stereotypical facial features, congenital heart disease, posterior embryotoxin, butterfly vertebrae, and renal disease. Most infants with ALGS present within the first 3 months of life with cholestasis; however, those with severe extrahepatic manifestations (usually caused by associated congenital heart disease) may present at birth or even be identified by prenatal US. Although many forms of congenital heart disease have been associated with ALGS (e.g., tetralogy of Fallot and transposition of the great arteries), the most common is peripheral pulmonary stenosis. The characteristic facial features are frequently difficult to appreciate in the neonatal period but include a prominent forehead and pointed chin, giving the face a triangular appearance, deep-set eyes with hypertelorism, and a saddle nose.

When cholestatic jaundice occurs in the first 6 weeks of life, care must be taken to discriminate ALGS from alternate etiologies of neonatal cholestasis, particularly BA and other treatable etiologies for which timely initiation of treatment may change outcome. Initial evaluation should include serum biochemistries, abdominal US, and echocardiogram when a heart murmur is identified. In ALGS, the conjugated hyperbilirubinemia is associated with elevated serum aminotransferases and GGT, reflective of the biliary involvement. If there is clinical concern for ALGS, a spinal radiograph should be obtained to evaluate for hemivertebra or butterfly vertebra, and an ophthalmologic evaluation for posterior embryotoxin is recommended.

Although a liver biopsy is not required for the diagnosis of ALGS when other stereotypical syndromic features are present, one should be performed when the diagnosis is in question. The histopathology in ALGS is characterized by bile ductular paucity; however, this is not pathognomonic. In the preterm infant the number of bile ducts is normally diminished, and hence care must be taken to not incorrectly make the diagnosis of pathologic paucity (Kamath, Piccoli, 2014) (Fig. 77.4). In term infants and older children, the normal bile duct to portal tract ratio ranges from

0.9 to 1.8; ratios less than 0.9 are suggestive of paucity. Given the normal developmental progression of the biliary system in infancy and the importance of excluding BA, infants with cholestatic jaundice and elevated GGT usually require liver biopsy and hepatobiliary scintigraphy and may require an intraoperative cholangiogram to verify patency of the extrahepatic biliary system.

Metabolic bone disease is especially striking in ALGS. Elevated ALP commonly reflects abnormal bone metabolism in addition to the biliary disease. Serum bile salt levels can be extremely elevated, even in the absence of jaundice, leading to intractable and refractory pruritus. Hypercholesterolemia and hypertriglyceridemia can lead to the development of xanthomas, most prominent on extensor surfaces and areas of minor trauma including the diaper area and plantar surfaces of feet, abdomen, and neck.

Treatment of ALGS is directed at improving or maintaining adequate nutrition, treating the complications if there is cholestasis, and supporting the cardiovascular health. The introduction of this section has details regarding nutritional management of cholestatic infants.

α -1 Antitrypsin Deficiency

α -1 Antitrypsin (A1AT) deficiency is the most common genetic cause of liver disease and affects approximately 1 in 2000 live births (Perlmutter, 1998; Perlmutter, 2000; Perlmutter, 2007). It is an autosomal dominant disorder that results in a reduction in α -1 antitrypsin, a serine protease produced in the liver whose role is to inhibit other proteases and elastases that can lead to cellular destruction. The genetic defect results in a single amino acid substitution within the A1AT protein, resulting in abnormal molecular folding, and inability of the protein to be processed beyond the Golgi apparatus. Excessive hepatic accumulation of the abnormal A1AT protein results in hepatocellular injury.

The clinical phenotype of A1AT deficiency includes both liver and pulmonary manifestations. Pulmonary disease generally manifests in adulthood, whereas liver involvement commonly presents in neonates. Liver disease in A1AT is most often

• **Fig. 77.4** Alagille Syndrome Histology. (A) Hematoxylin and eosin stain of a liver biopsy from a 3-month-old boy demonstrating loss of bile ducts in a portal triad. This bile duct paucity is accompanied by hepatocellular cholestasis. The hepatocytes also demonstrate swelling. (B) At 10 months of age, another boy was transplanted for Alagille syndrome. On hematoxylin and eosin stain, his liver demonstrated paucity of bile ducts in the portal triads. Mild hepatocellular cholestasis is also present in this biopsy.

characterized by cholestatic jaundice, but hepatosplenomegaly and ascites can also be seen in the most advanced cases.

A1AT deficiency is diagnosed by serologic testing and liver histology. The most specific serum test is A1AT phenotyping (Pi type). Although commonly used as a less costly and more widely available screening test, the serum levels of A1AT can be falsely elevated into the normal range in times of systemic inflammation or infection and so should not be used in the diagnosis of A1AT. A1AT variants are named according to their electrophoretic migration pattern (Pierce, Eradio, 1979). The normal protein is designated M, and the S and Z variants are the most common, leading to a reduction in serum A1AT. The homozygous PiZZ is named because it has the slowest gel migration and causes the most severe disease phenotype. Generally liver disease manifests only in PiZZ, PiSZ, or, rarely, PiMZ variants (Ranes, Stoller, 2005).

The classic, but not pathognomonic, histologic finding in A1AT deficiency is periodic acid-Schiff (PAS)-positive diastase-resistant eosinophilic globules within the hepatocytes, representing the accumulated abnormal protein trapped within the endoplasmic reticulum. Liver histology may also demonstrate bile duct destruction, proliferation, and, potentially, bile duct paucity, making it important to exclude BA and ALGS.

Although recombinant A1AT has been used for the treatment of the pulmonary manifestations, management of the associated liver disease is primarily supportive, as there are no specific or targeted therapies currently available. As in all disorders resulting in cholestasis, fat malabsorption is common with A1AT deficiency. Cholestatic infants usually benefit from MCT-rich formula to aid the fat absorption and supplementation with fat-soluble vitamins as needed. Additionally, ursodeoxycholic acid may be utilized to improve bile flow; however, no study has demonstrated clear benefit. Historically, breastfeeding was thought to be of some benefit; however, in a study comparing formula-fed with breastfed infants, no benefit was found (Udall et al., 1985; Labrune et al., 1989). To prevent acceleration of pulmonary manifestations, including early emphysema, avoidance of smoking and environmental pollution is critical.

For infants and children with end-stage liver disease, liver transplantation is indicated. As most A1AT is manufactured in the liver, the recipient assumes the donor's Pi phenotype and, posttransplant, experiences normal serum levels of the functional protein, decreased risk of pulmonary disease, and no chance of recurrent disease in the transplanted organ.

Cystic Fibrosis Liver Disease

While cystic fibrosis (CF) is common, affecting approximately 1 in 2500 births in North America, CF-related liver disease is uncommon in the neonatal period. It is estimated that less than 2% of infants with CF present with cholestasis (Narkowicz, Waasdorp Hurtado, 2014). Given the low incidence of CF-related liver disease in neonates, testing for CF beyond state-mandated newborn screens should be reserved for those infants in whom alternate causes of cholestasis have been excluded or in infants with other typical features of CF, including meconium ileus or inadequate weight gain despite theoretically adequate caloric intake.

Disorders of Bile Acid Synthesis

There are several steps in the synthesis of bile acids that may be disrupted, leading to an accumulation of hepatotoxic bile acid intermediates. Bile acid synthesis disorders are rare, with a prevalence

of 1 in 50,000 in the general population. In the neonatal period, phenotypes of bile acid synthetic disorders include acute hepatitis, acute liver failure, persistent cholestasis, and progressive chronic hepatitis.

Cholic acid and chenodeoxycholic acid are the primary bile acids in humans, and disruption at any step in their synthesis results in the accumulation of toxic intermediate metabolites. Liver injury associated with disorders of bile acid synthesis occurs secondary to direct hepatocellular injury from accumulation of toxic intermediates or secondary to the accumulation of cholesterol, drugs, and other toxins within the liver from abnormal bile excretion.

The most common clinical presentation of disorders of bile acid synthesis include neonatal jaundice, failure to thrive, hepatosplenomegaly, metabolic bone disease, and bleeding early in childhood. Some disorders are associated with progressive neurologic disease, manifesting with seizures, developmental delay, deafness, blindness, and neuromuscular weakness.

Laboratory testing in infants with bile acid synthetic disorders demonstrates normal or low serum bile acid levels, elevated serum aminotransferases, normal GGT, and complications of fat malabsorption, including fat-soluble vitamin deficiency. If serum bile acids are found to be low, urinary bile acids should be measured for identification of the particular synthetic defect. Liver biopsies are generally nonspecific and can demonstrate canalicular bile plugging, inflammation without bile duct proliferation, or giant cell transformation (Setchell, Heubi, 2006).

Treatment of inborn errors of bile acid synthesis focuses on supporting normal growth and supplementation of fat-soluble vitamins. Treatment with cholic acid is a preferred therapy for the most common disorders of primary bile acid synthesis because it suppresses the production of the toxic bile acid intermediates. Ursodiol is not indicated as it does not suppress production of abnormal bile acid intermediates.

Progressive Familial Intrahepatic Cholestasis

Progressive familial intrahepatic cholestasis (PFIC) is a group of autosomal recessive disorders characterized by defective bile export leading to cholestasis. This group of disorders is classified based on the genetic mutation, and they are named PFIC 1, PFIC 2, and PFIC 3. Liver disease in PFIC results from accumulation of bile salts within the hepatocytes leading to profound cholestasis, fat-soluble vitamin deficiency, and intractable pruritus.

PFIC 1, also known as Byler disease, is caused by a mutation in the gene *ATP8B1* on chromosome 18q21-22, which encodes for a protein flippase (FIC 1) that facilitates the flipping of aminophospholipids from the outer to inner canalicular membrane. As the gene is also expressed in many extrahepatic tissues, affected individuals may also have short stature, deafness, pancreatitis, and persistent diarrhea.

PFIC 2 results from a defect in the bile canalicular bile salt export pump (BSEP) caused by a mutation in the gene *ABCB11* on chromosome 2q24. BSEP is responsible for transporting bile acids from inside the hepatocyte to the canaliculus. Disruption of BSEP results in accumulation of bile acids within the hepatocyte resulting in severe cholestasis and rapid progression to end-stage liver disease. PFIC 2 presents earlier and is a more rapidly progressive liver disease than PFIC 1. Children with PFIC 2 have an increased risk of developing hepatocellular carcinoma, a risk that persists even after liver transplantation.

PFIC 3 is caused by a mutation in the gene *ABCB4* on chromosome 7q21, which encodes for multidrug resistance-associated

protein 3 (MDR3) and mediates flopping of aminophospholipids from the inner to outer canalicular lipid bilayer. Rather than a deficiency in bile acid export, patients with PFIC 3 have a deficiency in phospholipid export. The resultant bile lacks phospholipids, making the micelles unstable and toxic to bile ducts, leading to a progressive intrahepatic cholangiopathy. In contrast to PFIC 1 and 2, only a third of children with PFIC 3 present with cholestasis during infancy, with most presenting in later childhood and adolescence. When infants with PFIC 3 do present with liver disease, they commonly have cholesterol gallstones complicating their intrahepatic cholestasis.

Infants with PFIC generally have markedly elevated serum bile acid levels with only mildly elevated serum bilirubin. The characteristic biochemical markers of PFIC 1 and 2 are a normal or low GGT, normal serum cholesterol, and only mild transaminitis; however, specific diagnosis requires genetic testing. PFIC 3 presents with an elevated GGT in the absence of extrahepatic biliary obstruction. The intrahepatic cholestasis that is commonly seen in PFIC often progresses to end-stage liver disease.

Treatment for PFIC initially focuses on the nutritional management of cholestasis because of insufficient absorption of fat and fat-soluble vitamins. Additionally, aggressive treatment of debilitating pruritus with ursodiol, antihistamines, cholestyramine, rifampin, and opioid antagonists is often required. In refractory cases, treatment may include partial biliary diversion, interruption of the enterohepatic circulation by surgical ileal exclusion, and liver transplantation (Englert et al., 2007).

Congenital Hepatic Fibrosis

Congenital hepatic fibrosis (CHF) is a hereditary malformation of the bile ducts resulting from failure of remodeling during embryogenesis. It is an autosomal recessive disorder that may present in isolation but is more often seen as a feature of several syndromes, including Ivemark, Berdet–Biedl, Caroli, and Joubert syndromes, autosomal recessive polycystic kidney disease (ARPKD), and disorder of glycosylation type 1b.

Caroli syndrome is characterized by CHF and ductal ectasia with cystic dilation of intrahepatic ducts. Infants with CHF most commonly present with portal hypertension and splenomegaly, although some present with cholestasis caused by cholangitis. Characteristically, CHF is associated with normal transaminases and intact synthetic function despite advancing portal hypertension. When complicated with cholangitis, transient elevation of GGT and conjugated bilirubin are typically seen. Diagnosis of Caroli syndrome may be made by imaging with abdominal US with Doppler or magnetic resonance imaging (MRI) of the liver with magnetic resonance cholangiopancreatography. When associated with ARPKD, CHF can be diagnosed clinically, but if in isolation histologic diagnosis is necessary.

Treatment of CHF is aimed at treating complications of portal hypertension and preventing and treating cholangitis. Portosystemic shunting is commonly required to decompress advanced portal hypertension. In Caroli syndrome, focal cystic dilation may be amenable to liver lobectomy, but, if diffuse, liver transplantation is required.

Infections

Congenital or perinatal infections and sepsis are common causes of neonatal liver cholestasis, hepatitis, and sometimes liver failure. A careful history and physical examination may suggest infection

as an etiology of neonatal liver disease. For ill-appearing infants with cholestasis, a rapid evaluation for bacterial infection (such as sepsis or urinary tract infection) is recommended. Judicial selection of antimicrobials must be considered, as several are known to exacerbate cholestasis by displacing bilirubin from albumin (e.g., ceftriaxone) or cause direct hepatotoxicity (e.g., sulfamethoxazole/trimethoprim and fluconazole) (Murray and Horslen, 2014). In addition to common bacterial infections, TORCH infections (toxoplasmosis, rubella, cytomegalovirus, herpes, and syphilis) as well as infections with hepatitis B, parvovirus B19, adenovirus, or echoviruses can result in neonatal cholestasis and hepatitis. For more detail regarding diagnosis and specific treatments for congenital or neonatal infections, please refer to Section IX.

Parenteral Nutrition–Associated Liver Disease

Parenteral nutrition–associated liver disease (PNALD) is an important and common cause of hepatitis, cholestasis, and liver-related morbidity in the neonatal period. It is estimated that between 33% and 85% of premature infants who receive parenteral nutrition for more than 7 days develop PNALD (Duro et al., 2011; Koseesirikul et al., 2012). The primary phenotypic manifestation of PNALD in infants is cholestasis. When total parenteral nutrition (TPN) is utilized for a short duration, generally less than 2 weeks, the transient liver inflammation generally completely resolves. However, prolonged use increases the risk for irreversible and severe liver disease, which may ultimately result in liver failure (Nanji, Anderson, 1985; Beath et al., 1995). PNALD often presents as hepatic steatosis with elevated serum aminotransferases, cholelithiasis, and cholestasis. Several risk factors have been identified that contribute to the development of PNALD and include prematurity, low birth weight, lack of enteral feeding, sepsis, short gut syndrome, and necrotizing enterocolitis (Btaiche, Khalidi, 2002; Rangel et al., 2012). The diagnosis of PNALD in an infant receiving TPN is suggested by the presence of a serum conjugated bilirubin level less than 2 mg/dL and ALT greater than two times the upper limit of normal.

Management of PNALD includes early initiation and continuation of enteral feeding, lipid minimization to less than 1 g/kg per day, and prevention of infection. Ursodiol at a dose of 20 to 30 mg/kg per day in divided doses may be utilized to improve or stimulate bile flow (Kowdley, 2000; Chen, et al., 2004; Al-Hathlol et al., 2006). Additionally, the use of omega-6 fatty acid or fish oil–based, rather than soy-based, lipid formulations have been shown to be effective at resolving cholestasis (Murray and Horslen, 2014). Recognition and early intervention are required to prevent irreversible liver damage, which can progress to end-stage liver disease.

Metabolic Liver Disease

Inborn errors of metabolism often present with elevated serum aminotransferases, hepatomegaly, or metabolic derangements. There are several clinical phenotypes of metabolic liver disease, including acute liver failure, encephalopathy, cholestasis, and isolated hepatomegaly. Tables 77.2–77.3 summarize the clinical phenotypes of neonatal metabolic liver disease and etiologies of acute neonatal liver failure.

Disorders of Carbohydrate Metabolism

Galactosemia

Galactosemia results from an inability to metabolize galactose secondary to a deficiency in one of the following: galactokinase,

**TABLE
77.2****Common Clinical Presentations of Metabolic Liver Diseases in the Neonatal Period**

| Clinical Presentation | Metabolic Disorder | Laboratory Investigation |
|-----------------------|---|--|
| Acute liver failure | Galactosemia Tyrosinemia Hereditary fructose intolerance | Erythrocyte galactose-1-phosphate uridyl transferase activity, DNA mutational analysis Urine—succinylacetone Screen—urine reducing substances Genetic testing Enzyme activity analysis |
| | Mitochondrial defects Fatty acid oxidation defects Gestational alloimmune liver disease | Serum lactate, pyruvate Fibroblast enzymatic assay, acyl carnitine profile, genetic testing Ferritin, liver biopsy with C5b-9 staining |
| Encephalopathy | Fatty acid oxidation defects Organic acidemias Urea cycle defects | As above (ferritin, liver biopsy with C5b-9 staining) Urine organic acids Serum ammonia level, serum amino acid profile |
| | | |
| Cholestasis | Peroxisomal disorders | Specialized screening for urine metabolites such as very long chain fatty acids, pibecolic acid, phytanic acid, pristanic acid |
| | Lysosomal storage disorders | Liver biopsy, leukocyte glucocerebrosidase activity, genetic mutational analysis |
| Hepatomegaly | Glycogen storage diseases Lysosomal storage disorders | Liver or fibroblast enzymatic assay, genetic testing See above (liver biopsy, leukocyte glucocerebrosidase activity and genetic mutational analysis) |
| | | |

**TABLE
77.3****Causes of Neonatal Acute Liver Failure**

| | |
|--------------------------|--|
| Infections | Herpes simplex virus Human herpesvirus 6 Cytomegalovirus Adenovirus Influenza Hepatitis B Bacterial sepsis Enterovirus Parvovirus B19 Malaria |
| Metabolic/Genetic | Galactosemia Tyrosinemia type 1 Hereditary fructose intolerance Fructose 1,6-bisphosphatase deficiency Fatty acid oxidation defects Mitochondrial defects |
| Immune-Mediated | Gestational alloimmune liver disease Autoimmune hemolytic anemia with giant cell hepatitis Hemophagocytic lymphohistiocytosis |
| Vascular | Ischemia Heart failure |
| Toxic | Drugs Toxins |
| Neoplastic | Leukemia |

galactose-1-phosphate uridyl transferase (Gal-1-PUT), or uridine diphosphate galactose-4-epimerase. Gal-1-PUT deficiency is the most common cause of galactosemia and results in the inability to metabolize galactose into glucose-1-phosphate. It is an autosomal recessive disorder with an incidence of 1 per 60,000 live births (Squires, Heubi, 2014). Abnormal galactose metabolism results in accumulation of toxic metabolites in the liver, brain, kidney, and eye lens.

Classically, galactosemia presents within the first few weeks of life after infants ingest breast milk or milk-based formulas that contain lactose. Presenting symptoms may include failure to thrive, jaundice, vomiting, and diarrhea. Occasionally, infants may present acutely, with *Escherichia coli* sepsis with severe acidosis, jaundice, and coagulopathy. Additional clinical findings may include hepatomegaly, ascites, bleeding, hypotonia, edema, and bulging fontanelle. Although affected infants will spill reducing sugar in their urine (positive urine reducing substances) while still ingesting galactose, the gold standard of diagnosis is demonstration of a complete absence of Gal-1-PUT activity via a quantitative red blood cell (RBC) assay. Many newborn screens may identify variants of the disease, resulting in varying activity of Gal-1-PUT. It should be noted that, because the assay is of RBC enzyme activity, analysis post-RBC transfusion will give unreliable results.

Treatment of galactosemia centers on the immediate stabilization of the critically ill infant as well as urgent restriction of galactose from the diet. Treatment is generally supportive and involves intravenous fluids with glucose, vitamin K, antibiotics, and initiation of a soy-based (nongalactose-containing) formula. As infants graduate to solid food, continued avoidance of lactose-containing foods is recommended. Despite treatment, many children will have some degree of developmental delay.

Hereditary Fructose Intolerance

Hereditary fructose intolerance (HFI) is an autosomal recessive disorder characterized by a deficiency in fructose-1-phosphate aldolase (aldolase B), which is important in both glycolysis and gluconeogenesis, and plays a critical role in the metabolism of fructose. The incidence is approximately 1 per 20,000 live births (Squires, Heubi,

2014). Approximately 75% of dietary fructose is metabolized by the liver, with the remainder metabolized by the kidneys and small bowel. The deficiency in aldolase B leads to a toxic accumulation of fructose-1-phosphate and traps phosphate in an unusable form, thus depleting adenosine triphosphate (ATP) stores and, in turn, inhibiting normal gluconeogenesis and glycogenolysis.

Most infants with HFI are healthy until ingestion of fructose or sucrose (disaccharide of glucose and fructose). Upon ingestion of fructose they begin accumulating the toxic metabolites, developing metabolic derangements that lead to vomiting, hepatomegaly, and failure to thrive. Diagnosis may be suspected after a careful dietary history is obtained, and laboratory evidence of acute liver failure, hypoglycemia, and proximal renal tubular acidosis is found. Urine can be tested for the presence of reducing substances, as fructose in the urine will give a positive test, but this is not specific. Definitive diagnosis requires confirmation with genetic testing for mutations in the *ALDOB* gene, located at 9q22.3, or enzyme analysis from liver tissue.

Treatment of HFI requires prompt removal of dietary fructose and sucrose. Complete elimination is seldom achievable, and there are no established thresholds of required restriction. Additionally, as the severity of the enzyme deficiency is heterogeneous, some patients may develop chronic symptoms despite treatment (Stanbury, 1983). Fortunately, with nearly complete dietary restriction of fructose and sucrose, most children with HFI display normal growth and development.

Glycogen Storage Diseases

Glycogen is a glucose polymer that is primarily stored in the liver and muscle and is required for glucose homeostasis during fasting. There are 12 recognized glycogen storage diseases (GSD), but only types I, III, and IV primarily manifest as neonatal liver disease.

GSD type I, also known as von Gierke disease, named after its discoverer, Edgar von Gierke, is a rare autosomal recessive disease with an incidence of approximately 1 per 100,000 live births (Squires, Heubi, 2014). There are several defects that lead to the clinical manifestation of GSD type I; however, the end result is absence or decreased activity of glucose-6-phosphatase. Infants with GSD type I generally present with hepatomegaly and fasting hypoglycemia, often first noted when children begin to sleep more than 4 hours. Lactic acidosis, hyperuricemia, hyperlipidemia, hyperphosphatemia, neutropenia (specific to GSD type Ib), and bleeding secondary to platelet dysfunction are other clinical manifestations experienced by those affected with GSD type I.

Diagnosis is confirmed by DNA mutational analysis of the potentially affected genes. GSD Ia accounts for 80% of cases and results from mutation of *G6PC*, the gene for glucose-6-phosphatase, located on chromosome 17q21, and GSD Ib represents less than 20% of cases and results from mutations of the gene *G6PT1*, the G6P transporter. Prenatal diagnosis is possible via chorionic villus sampling.

Treatment in infancy consists of maintaining euglycemia with frequent feedings and continuous enteral feeds overnight with a high-glucose, low-fat formula. In older infants and children, a carbohydrate-balanced diet and frequent feedings that include the addition of cornstarch are recommended. Cornstarch provides a long-lasting source of glucose because it is slowly degraded by α -amylase and hence negates the need for hourly glucose intake. With adequate metabolic and glycemic control, children generally grow and develop normally.

GSD type III (Cori or Forbes disease) is an autosomal recessive disease that results from deficiency of the glycogen debranching

enzyme, amylo-1,6-glucosidase, and occurs in 1 in 100,000 live births. The presentation in infancy is similar to that of GSD type I, although the hypoglycemia is not usually as rapid and severe, and failure to thrive may be more prominent. The skeletal muscle (hypotonia) and cardiac manifestations (cardiomyopathy) occur later in childhood. Diagnosis is made by directly measuring the activity of amylo-1,6-glucosidase in the liver or, more recently, doing mutational analysis on the associated gene, *AGL*. Treatment mirrors that of GSD type I, with efforts to maintain euglycemia.

GSD type IV (Andersen disease) is an autosomal recessive disorder caused by a mutation in the *GBE1* gene, resulting in deficiency of glycogen branching enzyme; it affects roughly 800,000 individuals worldwide and accounts for 3% of the cases of GSD. GSD type IV may present prenatally with hydrops or postnatally with hypotonia, heart failure (secondary to cardiomyopathy), contractures, and muscle atrophy. Diagnosis is based upon the absence of branching enzyme activity in skin fibroblasts or detection of mutations in the *GBE1* gene. Treatment consists of liver transplantation when progression to end-stage liver disease has occurred (usually in the third decade of life); however, care must be taken in patient selection as extrahepatic manifestations may be life-limiting.

Disorders of Amino Acid Metabolism

Tyrosinemia Type 1

Tyrosinemia is an autosomal recessive disorder with an incidence of 1 in 100,000 live births. It results from deficiency of fumarylacetoacetate hydrolase, the enzyme responsible for the final step of tyrosine degradation (Squires, Heubi, 2014). Tyrosinemia generally presents acutely in the neonatal period and should be included in the differential of fulminant neonatal liver failure. Failure to thrive, vomiting, ascites, coagulopathy, hypoglycemia, and hyperbilirubinemia may be the initial presenting signs and symptoms. In older infants and children, a more chronic presentation typified by growth failure, Fanconi syndrome, and neurologic manifestations may develop. Children with tyrosinemia type 1 carry a long-term risk of developing hepatocellular carcinoma. Diagnosis is made by measuring elevated urinary succinylacetone.

Treatment in the neonatal period consists of correcting metabolic derangements, treating sepsis, and correcting coagulopathy, followed by the restriction of dietary tyrosine using specific formulas. Treatment with diet alone, however, results in less than 40% survival at 1 year of age (Holme, Lindstedt, 1998; McKiernan, 2006; Masurel-Paulet et al., 2008). Treatment with NTBC (2-(2-nitro-4-trifluoromethylbenzoyl)-1,3-cyclohexanedione, nitisinone) has been demonstrated to improve survival to greater than 85% at 1 year of age and is now the standard of care in the treatment of tyrosinemia (Mohan et al., 1999). NTBC works by reversibly inhibiting 4-hydroxyphenylpyruvate dioxygenase, hence preventing the formation of maleylacetoacetic acid and fumarylacetoacetic acid, the precursors to the hepatotoxic compound succinylacetone.

Maple Syrup Urine Disease

Maple syrup urine disease (MSUD), like other rare disorders of amino acid metabolism, is autosomal recessive and screened for on routine newborn screening tests throughout the United States. Caused by the deficiency in the branched chain α -ketoacid dehydrogenase complex, the disease results in accumulation of the branch chain amino acids and their toxic ketoacids. Most infants present with vomiting, acidosis, and evolving neurocognitive dysfunction or intermittent altered mental status. The disorder is

named from the particularly sweet odor, reminiscent of maple syrup, which emanates from the urine of affected infants. Laboratory analysis may reveal mildly elevated transaminases, hypoglycemia, and hyperammonemia. Diagnosis is made by the identification of excessive branched chain amino acids (valine, leucine, and isoleucine) in the serum. Treatment is dietary, with restriction of branched chain amino acids by limiting protein intake, supplementation with specialized formula, and care not to induce catabolism. The clinical course and natural history of MSUD and other disorders of amino acid metabolism are characterized by intermittent episodes of metabolic crises, including ketosis, acidosis, and hyperammonemia, which may be treated with intravenous glucose administration, arginine, and, rarely, dialysis. Liver transplantation may be considered for those patients in whom severe metabolic crises are threatening to cause evolving developmental delays.

Disorders of Organic Acid Metabolism

The autosomal recessive methylmalonic acid, isovaleric acid, and 3-hydroxy-3-methylglutaryl (HMG)-coenzyme A (CoA) lyase deficiencies are rare and make up disorders of organic acid metabolism. Most are screened for on routine newborn screening in the United States but are confirmed with the identification of a particular pattern of organic acids in the urine. Collectively, they present with metabolic crises, similar to MSUD. Treatment is largely by avoidance of catabolism and by tailored diets.

Fatty Acid Oxidation Defects

Fatty acid oxidation (FAO) is responsible for the production of the cellular energy that is required for normal cardiac and skeletal muscle function and glucose homeostasis. FAO largely occurs within mitochondria. The end result of FAO is the production of ketones, which serve as a critical energy source when glucose stores are depleted. Defects in FAO include: medium-chain acyl-CoA dehydrogenase deficiency (MCADD), long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency (LCHADD), HMG-CoA synthase deficiency, and carnitineacylcarnitine translocase (CACT) deficiency.

MCADD is an autosomal recessive disorder that affects the metabolism of medium-chain fatty acids and results in fasting hypoglycemia and accumulation of toxic acyl-CoA. The clinical presentation is generally recurrent lethargy, emesis, coma, and even death secondary to life-threatening hypoglycemia. Laboratory evaluation reveals hypoglycemia, hepatitis, hyperammonemia, hypoketosis, and hyperuricemia. Confirmation of diagnosis is made by fibroblast enzymatic assays or genetic testing. Treatment is avoidance of hypoglycemia, but infants are at risk of sudden death due to metabolic derangements, and many develop significant developmental delays.

LCHADD is an error of fatty acid metabolism that affects the mitochondrial trifunctional complex, the primary function of which is to metabolize long-chain fatty acids (found in oils and milk). The classic presentation of a neonate with LCHADD is acute onset of poor feeding in the newborn period, accompanied by lethargy, hypotonia, and hypoketotic hypoglycemia. Older children may go on to develop neuropathy and retinopathy. LCHADD in a fetus predisposes the mother to develop *hemolysis, liver dysfunction, low platelets* (HELLP) syndrome, and acute fatty liver of pregnancy. Diagnosis is suggested by newborn screening and confirmed by measuring LCHADD activity in fibroblasts or muscle or mutational analysis. Treatment is largely dietary, with a low-fat,

high-carbohydrate diet and supplementation with MCTs. Morbidity is high, despite dietary intervention.

HMG-CoA synthase deficiency results in the failure to form ketones in times of stress, resulting in hypoketotic hypoglycemia. Infants may present with hepatomegaly, encephalopathy, or coma in the setting of acute illness or fasting. Generally, serum aminotransferases are normal, as is serum lactate. Diagnosis is suggested by the absence of urinary ketones with normal acyl carnitine profile and confirmed by molecular testing. Treatment is largely avoidance of fasting.

CACT is necessary to transport long-chain fatty acids from the cytosol into the mitochondrion, which supports the production of ATP. Most patients with deficiency in CACT present in the neonatal period with hypoketotic hypoglycemia, hepatic dysfunction, cardiomyopathy, and seizures. Laboratory investigation often reveals hypoketosis, hypoglycemia, hyperammonemia, elevated creatinine kinase, elevated serum aminotransferases, low carnitine levels, and abnormal acyl carnitine profile. Diagnosis is confirmed by genetic testing. Treatment is dietary and involves a low-fat diet with supplementation of MCTs and carnitine. Morbidity and mortality are high in the presence of cardiomyopathy.

Urea Cycle Defects

One of the primary functions of the liver is ureagenesis, to detoxify ammonia, which is the end product of amino acid metabolism. The accumulation of ammonia and glutamine lead to hepatocellular and central nervous system dysfunction. The most common disorders of ureagenesis include ornithine transcarboxylase deficiency, carbamoyl phosphate synthase, and citrullinemia. These disorders generally present in the neonatal period with hyperammonemia and, potentially, cerebral edema, in the first few days of life. The clinical presentation may be confused with sepsis. Diagnosis is suggested by the presence of hyperammonemia with low serum blood urea nitrogen and typical patterns of abnormal elevations in serum amino acids. Diagnosis is confirmed by molecular genetic testing. Treatment should be directed by a metabolic specialist and largely focuses on maintaining serum ammonia within normal range, preventing catabolism, and utilizing a protein-restricted formula with one-half of the protein content as essential amino acids. Liver transplantation may be considered in patients with severe recurrent episodes of metabolic crises with hyperammonemia.

Mitochondrial Hepatopathies

Mitochondrial hepatopathies secondary to respiratory chain complex deficiencies may present in the neonatal period as acute liver failure. Additionally, mitochondrial disorders should be suspected in neonates who present in the first week of life with hypoglycemia, hypotonia, seizures, and evolving hepatic synthetic dysfunction. Diagnosis is suggested by elevated lactate and specifically with lactate-pyruvate ratios greater than 30. With evolving mitochondrial DNA mutational analysis some disorders may be identified; however, few targeted therapies are available. Liver transplantation may be considered if additional comorbidities do not suggest poor post-transplant survival.

Lysosomal Storage Disorders

Lysosomal storage disorders generally present with hepatosplenomegaly as well as an array of systemic symptoms. The most common

lysosomal storage disorders are Gaucher disease, Niemann–Pick disease type C (NPD-C), and lysosomal acid lipase deficiency.

Gaucher disease is an autosomal recessive genetic disease that results from the deficiency of a lysosomal enzyme, glucocerebrosidase, leading to an accumulation of glycolipids within lysosomes. The incidence is approximately 1 per 75,000 live births but is more prevalent in infants of Ashkenazi Jewish descent (Squires, Heubi, 2014). Clinical suspicion should be raised in infants who present with hepatosplenomegaly and normal to mildly elevated liver enzymes. Diagnosis is supported by liver biopsy, which demonstrates macrophages filled with lipid, also known as Gaucher cells; however, the diagnosis is confirmed by reduced glucocerebrosidase activity in leukocytes or by mutational analysis. Prenatal diagnosis is available by chorionic villus sampling or amniocentesis. Targeted treatment with enzyme replacement therapy with recombinant glucocerebrosidase is recommended for symptomatic children.

NPD-C is autosomal recessive and caused by mutations in *NPC1* and *NPC2*. These mutations result in impaired processing and transport of low-density lipoprotein (LDL) cholesterol, which clinically manifests as hepatosplenomegaly and progressive neurocognitive degeneration with dystonia, seizures, dysphagia, and ataxia. Laboratory findings characteristic of NPD-C include decreased high-density lipoprotein, hypertriglyceridemia, and increased LDL. Diagnosis is confirmed by fibroblast cell culture and genetic testing. Treatment is largely supportive, as bone marrow transplantation, liver transplantation, and lipid-lowering medications have not been shown to confer survival benefit.

Lysosomal acid lipase deficiency results in two distinct phenotypes: Wolman disease and cholesteryl ester storage disease (CESD). Both occur secondary to abnormal lysosomal accumulation of cholesteryl esters, triglycerides, and other lipids. Phenotype severity depends on the extent of reduction in lysosomal acid lipase activity. Wolman disease is the most severe manifestation of lysosomal acid lipase deficiency. Infants typically present in the first few weeks of life with failure to thrive, steatorrhea, hepatosplenomegaly, and jaundice. Death generally occurs within the first year of life. Diagnosis is suggested by calcifications of adrenal glands, cholestasis, elevated transaminases, liver synthetic dysfunction, and a normal plasma lipid profile. Liver biopsies have a characteristic orange-yellow appearance secondary to lipid and fat accumulation. CESD generally presents in older children or even in adulthood. Treatment is largely supportive, although trials of recombinant lysosomal acid lipase are available.

Gestational Alloimmune Liver Disease

Historically, gestational alloimmune liver disease (GALD) was referred to as neonatal hemochromatosis, a term used to describe the clinical phenotype of severe neonatal liver disease resulting from an inborn error of iron metabolism, causing hepatic and extrahepatic siderosis. Recently, advances in understanding of the pathogenesis debunk earlier suppositions that GALD results from primary iron overload. Evidence now suggests that iron overload is the phenotype that results from GALD (Bonilla et al., 2012; Whittington, 2012; Zoller, Kinsley, 2012). While nearly all nonhematopoietic iron overload is due to GALD, there are a few rare associations other than GALD. These include trisomy 21, mitochondrial DNA depletion syndrome, and bile acid synthetic defects.

The pathogenesis of GALD stems from complement-mediated hepatocyte injury and alloimmunity activated by maternal immunoglobulin G (IgG) (the only immunoglobulin that freely crosses the placenta). Once sensitization has occurred, maternal antifetal hepatocyte IgG binds to fetal liver antigen. Subsequently,

complement-mediated destruction of fetal hepatocytes results in neonatal liver mass that is 10%–25% of normal. The unaffected fetal liver normally produces hepcidin to regulate placental iron delivery (Bonilla, 2012), but in GALD the drastically reduced amount of hepcidin fails to appropriately regulate iron influx, resulting in iron overload.

GALD should always be suspected in infants who manifest prenatal or neonatal liver disease, especially in liver failure. Infants with GALD are typically sick at birth. In the fetal period, oligohydramnios or intrauterine growth restriction are common. Affected newborns generally present in the neonatal period with acute liver failure with hypoglycemia and coagulopathy or, more rarely, with cirrhosis. Cholestasis generally evolves over time but is not present at birth. Laboratory findings may include normal to slightly elevated ALT, elevated ferritin (n/mL) levels (generally >800 but commonly exceeding 15,000), alpha fetoprotein (ng/mL) greater than 80,000 but typically greater than 300,000, and iron saturation greater than 90%. Imaging may demonstrate extrahepatic siderosis effecting the pancreas, myocardium, thyroid, and salivary glands.

Diagnosis is suggested by liver biopsy demonstrating reduced hepatocyte volume and the presence of C5b-9 complex on immunohistochemistry (Pan et al., 2010). Biopsies may also show hepatocyte collapse, fibrosis, and siderosis (Fig. 77.5). However, demonstration of extrahepatic siderosis is necessary to confirm the diagnosis. This may be accomplished by tissue biopsy or MRI. Generally, it may be preferable to obtain mucosal tissue (submucosal glandular biopsy). This may be followed by MRI if the biopsy is negative and diagnosis is still suspected. Unfortunately, GALD is often diagnosed at autopsy where extrahepatic siderosis is observed.

Treatment attempts to block existing antibody action by administration of high-dose intravenous immunoglobulin (IVIG) (1 g/kg) as well as to remove existing antibody with double-volume exchange transfusion. This regimen has been shown to improve survival to between 75% and 80% without liver transplantation (Rand et al., 2009). Before this treatment regimen, outcomes were very poor with older medical therapies such as iron chelation and antioxidants, which have no role in current treatment recommendations. GALD remains a common indication for liver transplantation in the neonatal period; however, transplantation in these patients is complicated by small infant size and multiorgan failure.

Because of the rapid progression and high mortality associated with GALD, if it is suspected, an infant should receive a dose of IVIG immediately, even before the diagnostic work-up is complete. Side effects of IVIG are minimal, and IVIG has minimal impact on the natural history of alternate causes of neonatal liver failure. If diagnosis is confirmed, then the double-volume exchange transfusion should be employed followed by a second dose of IVIG.

The probability of GALD diagnosis in each subsequent infant born to a mother whose previous child was born with GALD is greater than 90% (Whittington, Kelly, 2008). However, GALD is thought to be congenital and familial but not hereditary (Whittington, 2007). Evidence for prevention of GALD is evolving. Given the high risk of subsequent infants developing GALD following an index birth of an affected infant, all mothers should be treated during pregnancy with recurring infusions of IVIG at 14 weeks gestational age, 16 weeks, and weekly from 18 weeks until delivery (Whittington, Hibbard, 2004).

Vascular Malformations

Vascular malformations of the liver generally present in the neonatal period if they are associated with cutaneous malformations or result

• **Fig. 77.5** Gestational Alloimmune Liver Disease Histology. (A) Hematoxylin and eosin stain of a liver demonstrating pericellular fibrosis. Many hepatocytes contain pigment, some of which is hemosiderin, and some of which is bile. (B) The corresponding Gomori iron stain shows iron deposition within hepatocytes. (C) Iron stain demonstrating iron deposition in the pancreas acinar epithelial cells. (D) Iron stain demonstrating iron deposition in thyroid follicular cells.

in significant systemic shunting of blood. Types of shunts may include hepatic artery to hepatic vein, hepatic artery to portal vein, or from portal vein to systemic circulation (portosystemic shunts).

Arteriovenous Malformations

Arteriovenous malformations that shunt large volumes of blood may present in the neonatal period with anemia, heart failure, portal hypertension, or hepatomegaly depending on the vascular involvement. Treatment includes embolization, surgical ligation, or resection. Liver transplantation is reserved for those lesions that are not amenable to more limited surgical intervention and that result in life-threatening complications.

Congenital Portosystemic Shunts

Congenital portosystemic shunts allow for intestinal venous blood to bypass the liver and shunt directly into the systemic venous system. They may be either intrahepatic or extrahepatic in origin (Fig. 77.6–Fig. 77.7). Extrahepatic portosystemic shunts are known

as “Abernathy malformations” (Fig. 77.8). Persistence of fetal circulation with a patent ductus venosus may allow for intrahepatic shunting from the left portal vein to a hepatic vein.

Portosystemic shunts are most commonly identified incidentally on abdominal imaging in individuals with portal hypertension or other vascular malformations. If diverting significant portal blood flow past the liver, they may lead to elevated serum ammonia. Portal hypertension is not usually seen with portosystemic shunts.

Treatment of congenital portosystemic shunts varies and depends on the severity of clinical sequelae. Several may close spontaneously; however, those that are contributing to encephalopathy and subsequent developmental delay or cardiopulmonary compromise should be considered for closure. Techniques may include embolization, surgical ligation, or, rarely, liver transplantation (Ohnishi, 2005; Gillespie et al., 2006).

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT) is an autosomal dominant disease characterized by mucosal and cutaneous

• **Fig. 77.6** Congenital Intrahepatic Arteriportal Fistula. (A) Coronal maximum intensity projection image from an arterial phase computed tomography scan of the abdomen demonstrates a fistulous connection between the left hepatic artery (*white arrow*) and left portal vein (*black arrow*) with a large associated aneurysm. Digital subtraction angiogram images of the celiac axis in arterial (B) and delayed (C) phases redemonstrate the arteriportal fistula supplied by the left hepatic artery (*white arrow*) with shunting into the portal venous system (*black arrow*). (Images courtesy of Dr. Eric Monroe, Interventional Radiology, Seattle Children's Hospital, Seattle, Washington.)

telangiectasias and visceral vascular malformations. The visceral organs most commonly affected include the lungs, liver, intestine, and brain. The prevalence is estimated to be approximately 1 per 10,000 live births. Diagnosis of HHT is based on fulfilling greater than three of four clinical criteria and genetic testing. The clinical criteria include spontaneous, recurrent epistaxis, multiple cutaneous and oral cavity telangiectasias, the presence of visceral vascular lesions, and a first-degree relative with HHT.

Most infants with HHT will present with high-output heart failure and potentially portal hypertension secondary to arteriportal

shunting. An ischemic cholangiopathy may result if hepatic arterial blood shunts away from bile ducts.

As with all liver-associated vascular lesions, diagnosis is accomplished by Doppler-enhanced US of the abdomen. In the case of HHT, US most commonly demonstrates a dilated hepatic artery with elevated hepatic artery flow and intrahepatic vascularity. On computed tomography (CT), the presence of multiple telangiectasia leads to heterogeneous enhancement of the liver. Liver biopsy carries high risk of bleeding.

Liver transplantation may be considered in the setting of heart failure, biliary ischemia, or severe portal hypertension.

• **Fig. 77.7** Congenital Intrahepatic Portosystemic Shunt. (A) Sagittal image from a venous phase computed tomography scan of the abdomen demonstrates an anomalous portosystemic shunt between the anterior division of the right portal vein (*white arrow*) and middle hepatic vein (*black arrow*). (B) Right anterior oblique digital subtraction angiogram image following trans-shunt catheterization of the portal vein redemonstrates the broad portosystemic shunt between portal vein (*white arrow*) and middle hepatic vein (*black arrow*). (Images courtesy of Dr. Eric Monroe, Interventional Radiology, Seattle Children's Hospital, Seattle, Washington.)

• **Fig. 77.8** Abernathy Malformation. (A) Axial image from a late arterial phase computed tomography (CT) scan demonstrates a craniocaudal course of the portal vein (*white arrow*) and absent portal vein within the hepatic hilum. (B) Multiplanar reformat image from the CT confirms an abnormal course of the portal vein (*black arrow*) draining to the right atrium, parallel to the inferior vena cava (*white arrow*). (Images courtesy of Dr. Eric Monroe, Interventional Radiology, Seattle Children's Hospital, Seattle, Washington.)

Infantile Hepatic Hemangiomas

Infantile hepatic hemangiomas (IHHs) are the most common benign tumor of infancy, affecting as many as 1%–2% of newborns and upwards of 10% of infants by 1 year of age (Boon et al.,

1996). Most infants present with associated cutaneous or subcutaneous lesions; however, many present with isolated vascular lesions of the liver, brain, and lungs. IHH should be suspected in infants with five or more cutaneous hemangiomas, and this physical finding should prompt investigation for visceral involvement.

IHH is the most common pediatric tumor of the liver and may be characterized as focal, multifocal, or diffuse. Most infants with IHH present before 6 months of age and experience initial progression of the size of lesions from birth to 12 months, followed by a period of regression and involution by about 2 to 10 years of age.

Focal IHH is usually incidental and may be initially seen on prenatal US. They are not associated with cutaneous findings and are typically asymptomatic; larger lesions may lead to high-output heart failure. Diagnosis is by US imaging, identifying a hyperechoic or hypoechoic lesion with heterogeneous echotexture with vascular flow on Doppler interrogation. On MRI, lesions are noted to be hypointense on T1-weighted images and hyperintense on T2-weighted scans with centripetal enhancement with gadolinium contrast.

Multifocal and diffuse IHH are associated with multiple cutaneous hemangiomas. Multifocal IHH is typically not apparent at birth but presents within the first few weeks of life when the hemangiomas become more prominent. Symptomatic infants present with hepatomegaly, heart failure, anemia, and occasionally thrombocytopenia secondary to consumption, hemorrhage, or thrombosis within the hemangioma. Rarely, hemangiomas may stimulate inactivation of thyroxine, resulting in hypothyroidism. Occasionally, rupture of hemangiomas may result in intraperitoneal hemorrhage. US and MRI imaging are similar to that of focal IHH but with more numerous lesions. Treatment is reserved for symptomatic infants, as asymptomatic infants may be observed and followed with serial imaging. Medical therapy employs propranolol at a dose of 1 to 3 mg/kg per day, continued until the proliferation phase is completed around 9 to 12 months of age. Second-line treatments for propranolol failures include steroids, vincristine, and alfa 2a interferon (Leaute-Labreze et al., 2008; Mazereeuw-Hautier et al., 2010). Embolization or surgical resection may be utilized if medical therapy fails or in the setting of significant organ dysfunction. Liver transplantation has been performed in critical clinical circumstances without other options (Christison-Lagay et al., 2007; Dickie et al., 2009). Rarely, multifocal IHH may be associated with hepatic angiosarcoma.

Liver Masses

Hepatoblastoma

While many solid and cystic tumors of the liver may present in the neonatal period, the most common malignant tumor is hepatoblastoma. Risk factors for the development of hepatoblastoma include prematurity, low birth weight, familial adenomatous polyposis, trisomy 18, GSD Ia, Beckwith–Wiedemann syndrome, and Li–Faumeni syndrome. Hepatoblastoma most commonly presents as an abdominal mass associated with weight loss, abdominal pain, and decreased oral intake. Diagnosis is made by typical radiologic findings, including a well-defined but heterogeneous mass that may have areas of necrosis, hemorrhage, or calcification. MRI is the preferred mode of imaging. Biopsy to differentiate epithelial subtype (fetal, embryonal, macrotrabecular, and small cell undifferentiated) is required. Treatment consists primarily of

resection, augmented by chemotherapy; when not resectable, liver transplantation may be considered.

Congenital Hepatic Cysts

Congenital hepatic cysts are one of the most common benign liver masses of infancy. With modern imaging techniques, simple hepatic cysts are frequently diagnosed prenatally by US. There is a wide spectrum of pathologies resulting in simple hepatic cysts. Simple cysts are generally thought to develop from aberrant bile ducts and are not generally associated with cystic lesions of other organs (Rogers et al., 2007). They are characterized by a layer of cuboidal or columnar epithelium surrounding a collection of serous fluid. Most simple hepatic cysts are incidental, asymptomatic, do not require intervention, and may shrink or resolve over time. It is recommended that periodic, serial USs be utilized to survey for interval growth or resolution. Indications for surgical intervention include interval growth, large size, which may cause compression of nearby structures or cause risk for rupture, or those that become symptomatic (Rogers, 2007).

Developmental Hematology

SANDRA E. JUUL AND ROBERT D. CHRISTENSEN

KEY POINTS

- Pluripotential stem cells sustain hematopoietic function throughout a person's lifetime; the fate of developing cells is influenced by the microenvironment.
- The site of erythropoiesis changes over development, progressing from the yolk sac to the aortogonadomesonephron, to the liver, and then to the bone marrow. Erythropoietin (Epo) is the principal factor regulating secondary erythropoiesis.
- Hemoglobin tetramers change over development. Oxygen affinity decreases as hemoglobins switch from embryonic to adult forms.
- The optimal hematocrit trigger for neonatal transfusion remains unknown because the benefits and risks of transfusion at any given hematocrit remain unproven.
- The need for transfusions in the neonatal intensive care unit can be reduced by delayed cord clamping or cord milking, reducing phlebotomy-related losses, and using erythropoiesis-stimulating agents (Epo or darbepoetin)
- Most platelet transfusions given in the neonatal intensive care unit are prophylactic, meaning that they are transfusions in nonbleeding neonates with low platelet counts. The platelet count at which the benefits of platelet transfusion outweigh the risks is uncertain. The "platelet mass" (platelet count times mean platelet volume) may provide a better transfusion trigger than the platelet count alone. In general, 10–20 mL of single donor platelets per kilogram should raise the platelet count by more than 100,000/ μ L. Use of volume-reduced or pooled platelets should be avoided because processing results in platelet activation and decreased function.

Introduction to Embryonic Hematopoiesis

Hematopoiesis is the process by which self-renewing multipotential stem cells give rise to all of the differentiated blood cells (Fig. 78.1). This process involves the coordinated expression of growth factors, some of which act on primitive progenitors that can give rise to multiple cell lineages and others that support clonal maturation of lineage-committed multipotential hematopoietic stem cells (HSCs). Hematopoiesis begins in the embryo, with the first lymphoid progenitors emerging within the embryo and yolk sac before stem cell detection at embryonic day 7.5 (Lin and Yoder *et al.*, 2014). By day 10 HSCs are present in the aortogonadomesonephron and activity then shifts to the liver and finally to the bone marrow (Song *et al.*, 2016). Each cell lineage undergoes

developmental changes that are unique and specific (Yoder, 2014). Details of these systems and the resulting clinical effect of these changes are reviewed in the following chapters.

Stem Cell Biology

Pluripotential stem cells sustain marrow function throughout a person's lifetime. A unique characteristic of these cells is that their direct offspring include at least one identical daughter cell, thus perpetuating the population. In contrast, progenitor cells are more differentiated and give rise only to cells more differentiated than themselves. The fate of any particular developing cell is determined in large part by its microenvironment.

The developmental changes in the number, function, and location of HSCs are of interest to transplantation biologists and gene therapists. The proliferative capacity of HSCs differs with the anatomic source of the cells and with the age at which the cells are harvested. The sensitivity of these cells to recombinant cytokines also changes with age. Improving the understanding of the ontogeny of these cells may be helpful in optimizing their clinical use.

Embryonic and fetal HSCs are capable of repopulating adult organisms (Easterbrook *et al.*, 2016). In contrast, transplanted adult stem cells have a lower capacity for self-renewal, sometimes resulting in late graft failure. This might be because stem cells harvested from adults continue to express the adult differentiation program, even if transplanted into a neonatal environment, indicating an irreversible change in gene expression (Dziedosz *et al.*, 2016). Other explanations for the decrease in proliferative potential may have to do with DNA damage over time and loss of telomere repeats with each stem cell division, limiting the replicative potential (Warren and Rossi, 2009).

Ongoing research focuses on optimizing stem cell harvesting techniques. Cell-surface markers, which are dependent on cell maturity and gestational age, are often used to identify and separate HSCs with use of monoclonal antibodies and fluorescence-activated cell sorting analysis. For example, CD34, a cell-surface sialomucin, is an antigen commonly used to select HSCs and early erythropoietic progenitor cells. Combining CD34 positivity with the absence of lineage-specific markers allows selection of a population highly enriched for cells desired for transplant. Research is also focused on optimizing stem cell harvest sites. Both bone marrow and umbilical cord blood are rich in stem cells and have long been used as sources of progenitor cells. The collection of stem cells

• **Fig. 78.1** Overview of Hematopoiesis. Hematopoietic lineages are outlined in this simplified overview of hematopoiesis. *BFU-E*, Burst-forming unit–erythroid; *BFU-MK*, burst-forming unit–megakaryocyte; *CFU-E*, colony-forming unit–erythroid; *CFU-Eos*, colony-forming unit–eosinophil; *CFU-MK*, colony-forming unit–megakaryocyte; *CFU-GM*, colony-forming unit–granulocyte–macrophage; *NK*, natural killer; *PMN*, polymorphonuclear leukocyte. (Courtesy of Alexander R. Vermillion.)

from peripheral blood by stimulated apheresis, with ex vivo expansion of select populations, is now also an option (Brugger et al., 2000).

Umbilical cord blood (UCB) can be harvested as a source of HSCs and used for transplant in patients with marrow failure, malignancy, or immunodeficiency (Alfraih et al., 2016; Kekre and Autin, 2016). Hematopoietic progenitor cells in UCB tend to have a high proliferation index compared with cells harvested from adult marrow (Schoemans et al., 2006). Because of the immaturity of the UCB cells, HLA matching is less stringent for UCB, allowing more efficient donor unit identification compared with a bone marrow registry (Barker et al., 2002). This feature also allows improved matching ability for patients in minority ethnic populations since bone marrow registry matches are frequently in short supply. Promising strategies to increase cells available for transplant include combining multiple units of UCB (Barker et al., 2005) and ex vivo expansion of UCB units.

The first successful use of UCB for HSC transplant purposes was in 1989, between HLA-identical siblings, for severe aplastic anemia from Fanconi anemia (Gluckman et al., 1989). Since then, thousands of UCB transplants have been performed to treat malignancies such as acute lymphoblastic leukemia, acute myeloid leukemia, and chronic myeloid leukemia; bone marrow disorders such as Fanconi anemia; immunodeficiencies such as severe combined immune deficiency; metabolic disorders; and hemoglobinopathies (Kekre and Antin, 2016).

UCB can be stored in public or private commercial banks. Donation of harvested cells to public UCB banks allows storage in a central repository available to all individuals in need of

transplant. Private banking makes the stored UCB available at a cost for future use by individuals or a family. However, there is a low likelihood of any one individual needing an autologous UCB transplant (Roura et al., 2015).

Delaying cord clamping by 60 seconds increases the blood volume of the neonate and increases the endowment of iron. In theory, this practice might result in insufficient UCB remaining for banking. The Canadian Task Force on Preventive Health Care suggests that delayed cord clamping has significant benefits for the neonate and that sufficient blood typically remains in the umbilical cord and placenta after delayed clamping for UCB banking. The task force suggests that both techniques can generally be accomplished (Armson et al., 2015).

Developmental Aspects of Erythropoiesis

Erythropoiesis is the process of perpetual production of red blood cells (RBCs). Serial adaptations occur throughout development so as to meet the changing oxygen demands of the embryo, fetus, and neonate. The type of cells produced, the locations in which they are produced, and even the microenvironments within these locations change as development proceeds (Fig. 78.2). The molecular mechanisms involved in instituting, regulating, and maintaining these adaptations are complex.

Primitive and Definitive Erythropoiesis

During development, two types of RBCs are formed: primitive and definitive erythrocytes. The liver is the primary organ of

• **Fig. 78.2** Changing Sites of Hematopoiesis During Human Gestation. Fetal gestation is shown in months along the *central horizontal arrow*. The timing of significant events during hematopoiesis is shown, beginning with primitive erythropoiesis and megakaryocytopoiesis in the yolk sac and ending with definitive hematopoiesis in the bone marrow during late gestation. AGM, Aortogonadomesonephron.

hematopoiesis during fetal life, but primitive RBCs are first formed in the yolk sac (Yoshimoto and Yoder, 2009). Large primitive RBCs are produced in blood islands of the yolk sac days after implantation of the embryo. These cells enter the newly formed vasculature of the embryo, where they continue to divide and differentiate for several days. This process is only minimally responsive to Epo (Palis, 2014). Primitive erythroblasts are large ($>20\ \mu\text{m}$), CD34 negative, and contain predominantly embryonic hemoglobin. Hemoglobin synthesis continues until cell replication ceases (Boussios and Bertles, 1988). In mice a transition to definitive erythropoiesis occurs at embryonic day 13.5 (full gestation is 21 days). Definitive erythropoiesis is characterized by smaller ($<20\ \mu\text{m}$) CD34-positive erythroblasts, which produce fetal and adult hemoglobins, extruding their nuclei when mature. Unlike primitive erythropoiesis, this process is dependent on Janus kinase signal transduction and Epo stimulation (Neubauer et al., 1998). Primitive erythroblasts normally undergo apoptosis, becoming extinct during fetal life, whereas definitive erythroblasts are able to self-renew (Dieterlen-Lievre, 1997).

Switch of the Primary Site of Erythropoiesis

Humans have four main sites of embryonic and fetal erythropoiesis—yolk sac, aorta (ventral aspect), liver, and marrow. In rodents the spleen is also an important site of hematopoiesis, but there is no evidence for this in healthy humans (Calhoun et al., 1996). Studies using an in vitro embryonic stem cell differentiation system showed that endothelial cells, primitive hematopoietic cells, and definitive blood-cell colonies arise from a common fetal, liver,

kinase-1 (Flk-1)-expressing progenitor (Lancrin et al., 2009). Between embryonic day 8 and embryonic day 11.5, runt-related transcription factor 1 is required for the formation of HSCs and their progenitors. Primitive progenitor cells first develop in the yolk sac, followed by the rise of definitive progenitors, also in the yolk sac (Palis, 2008). Another source of the early definitive progenitors is the ventral aspect of the embryonic aorta (Tavian and Peault, 2005; Palis, 2008). Once circulation is established, progenitors from all lines are detected in the blood, then in the liver, and finally in the marrow (Tavian et al., 2001).

Yolk Sac

The yolk sac is an extraembryonic structure that can be subdivided into the primary and secondary yolk sac. The primary yolk sac is transient and has no known hematopoietic function. In humans it forms by proliferation and differentiation of primitive endodermal cells 7 to 8 days after conception. These endodermal cells give rise to mesodermal precursors (intermediate cells). The primary yolk sac then collapses into small vesicles, and the secondary yolk sac is formed from its remnants at 12 to 15 days after conception. By 16 to 19 days, primitive erythropoiesis is found in the human yolk sac (Kelemen and Janossa, 1980; Kennedy et al., 1997). The secondary yolk sac is an active site of protein synthesis, nutrient transport, and hematopoiesis (Enders and King, 1993). Primitive hematopoietic cells, adherent to surrounding endothelial cells, are first observed at day 16 in the mesodermal layer. These hematopoietic–endothelial cell masses have been described as *blood islands*. As maturation proceeds, these blood islands migrate toward each other, merging to form a network of capillaries. Small clusters of undifferentiated

cells, the hemangioblasts, and clusters of primitive erythroblasts are observed in the small vessels present at this developmental stage (Enders and King, 1993). As differentiation proceeds, endothelial and hematopoietic cell lineages emerge. These cell types share common molecular markers and responsiveness to a cohort of growth factors, and, depending on the microenvironment, can be derived from a common stem cell in culture (Eichmann et al., 1997; Lux et al., 2008; Lancrin et al., 2009).

After the sixth week after conception, definitive erythroblasts are found in the yolk sac. A decline in yolk sac hematopoiesis is observed after the eighth week (Enders and King, 1993). Yolk sac–derived hematopoietic cells have more restricted potential *in vivo*, as only RBCs and macrophages are present in the yolk sac (Enzan, 1986), while progenitor cells in the liver develop into the full spectrum of hematopoietic cells. However, when yolk sac–derived stem cells are cultured *in vitro* or are transplanted, they are multipotent, illustrating the importance of the microenvironment in the development of committed cell lineages.

Aortogonadomesonephron

Another site of early erythropoietic activity in the developing human embryo is the ventral aspect of the aorta, in the periumbilical region (Tavian and Peault, 2005). At around the 23rd postconceptional day in humans, the multipotent hematopoietic progenitor cells in this region are more numerous than in the yolk sac or the liver. By day 40 of gestation, hematopoiesis in this site is concluded.

Liver

A short time after the onset of blood circulation (week 4 to week 5 of gestation), erythropoiesis begins in the liver (Kelemen and Janossa, 1980). As in the yolk sac, primitive erythroblasts initially predominate. However, over the next 4 weeks, definitive erythrocytes become the predominant RBC form. During this time the liver mass increases 40-fold, with hematopoietic cells constituting 60% of the liver by week 11 to week 12 (Thomas and Yoffey, 1964). Meanwhile, other hematopoietic cell types are also produced in the liver. Early in this process (5 weeks), macrophages predominate, with approximately one granulocyte to every nine macrophages (Slayton et al., 1998b). In contrast to the yolk sac, during the period of peak hepatic hematopoiesis (week 6 to week 18), production of all hematopoietic cell lines (erythrocytes, macrophages, megakaryocytes, granulocytes, and lymphocytes) occurs. Between 18 and 21 weeks of gestation, hematopoiesis in the liver diminishes, but the liver continues as an erythropoietic organ until term.

Bone Marrow

As hepatic hematopoiesis diminishes, the bone marrow becomes the primary site of erythropoiesis and remains so throughout postnatal life. The process of erythropoiesis in marrow begins at about 8 weeks, again with primitive erythrocytosis (Kelemen and Janossa, 1980). Over the next few gestational weeks, a switch to definitive erythropoiesis occurs, and by 14 weeks, only definitive erythroblasts are present. As with the liver, production of all hematopoietic cells occurs in bone marrow. Erythropoietic cells constitute a maximum of 35% of total bone marrow cells at week 12 of gestation, falling to between 20% and 30% thereafter (Charbord et al., 1996).

Factors Influencing the Sites of Erythropoiesis

The microenvironment at each site of hematopoiesis influences the type and timing of hematopoietic development. The microen-

vironment includes hematopoietic growth factors and cytokines, as well as the extracellular matrix in which the cells proliferate.

Growth factors are thought to act mainly as permissive and/or selective signals, allowing already committed cell types to proliferate and differentiate. Growth factors important for definitive erythropoiesis include Epo, stem cell factor, interleukin (IL)-3, thrombopoietin (TPO), and possibly insulin and insulin-like growth factor I, both of which act as nonessential survival factors for CD34⁺ cells (Ratajczak et al., 1998). These growth factors work in concert to promote definitive erythropoiesis. However, Epo is the primary growth factor: in the absence of Epo signaling, as in the case for both Epo-null and Epo receptor-null mutations, definitive erythropoiesis does not occur. Null mutations of either Epo or its receptor are lethal at 13.5 days of gestation in the mouse, because of severe anemia.

Extramedullary Hematopoiesis

Extramedullary hematopoiesis can occur after the bone marrow has been established as the primary site of erythropoiesis. Diseases inducing this occurrence include hemolytic conditions, congenital rubella, cytomegalovirus infection, and parvovirus B19 infection. Extramedullary hematopoiesis can occur in the liver, spleen, adrenal glands, pancreas, thyroid, endocardium, testes, uterus, skin, or brain (Yamamoto et al., 2016). When the skin is involved in a neonate, the classic “blueberry muffin” rash is seen, typical of congenital rubella or cytomegalovirus infection.

Ontogeny of Erythrocytes

The earliest precursor cells specific to the erythroid lineage are the burst-forming unit–erythroid (BFU-E) cells. BFU-E cells have low numbers of Epo receptors (Sawada et al., 1990) and respond to Epo, as well as granulocyte–macrophage colony-stimulating factor (GM-CSF), and IL-3. As these cells mature into erythroid colony forming unit–erythroid and proerythroblasts, they become highly dependent on Epo, which is reflected by the high density of Epo receptors on the cell membrane (up to 1000 per cell) (Broudy et al., 1991). Mature erythroblasts have fewer Epo receptors and are less sensitive to Epo stimulation, and reticulocytes and erythrocytes have no Epo receptors and are unresponsive to Epo. The principal functions of mature erythrocyte metabolism are to maintain adequate adenosine triphosphate (ATP) stores, to produce reducing substances to act as antioxidants, and to produce 2,3-diphosphoglycerate (2,3-DPG), which modifies the oxygen affinity of hemoglobin.

Important developmental changes occur in hematocrit, reticulocyte count, and RBC morphology, membrane content, deformability, life span, and metabolism. Over the course of gestation, there is an expected rise in hematocrit, from (36 ± 3)% at 18 to 20 weeks of gestation (fetal samples) to (61 ± 7)% expected at term birth. To maintain this increase in hematocrit and blood volume (up to 7 mL/day during the last trimester), the production of approximately 50 × 10⁹ erythrocytes per day is required. During this same period of fetal development, erythrocyte size (the mean cell volume) decreases from 134 ± 9 femtoliter (fL) to 119 ± 9 fL (Christensen et al., 2008). At term the mean cell volume is larger than that of normal healthy adults and drops postnatally, reaching a nadir at 4 to 6 months. It then increases to reach adult values (88 ± 8 fL) by approximately 1 year.

Reticulocytes are near mature erythrocytes released from the bone marrow into the circulation. Although the nucleus has been

extruded, they retain cytoplasmic organelles such as ribosomes, mitochondria, and Golgi bodies for approximately 24 hours. These newly released cells can be differentiated from mature RBCs by manual methods that involve staining with new methylene blue or brilliant cresyl blue, which stain the nucleic acid within the cells. They can also be enumerated by electronic means that involve flow-cytometric gating of cells that are larger and contain more nucleic acid than mature RBCs. The reticulocyte count can be used to assess the level of erythrocyte production, because high values indicate active erythropoiesis, while low numbers indicate low levels of erythropoiesis. At birth, reticulocyte counts in preterm infants tend to be higher than in term infants (400,000/ μ L–550,000/ μ L vs 200,000/ μ L–400,000/ μ L) (Henry and Christensen, 2015a). Absolute reticulocyte counts, reticulocyte percentage of total RBCs, and corrected reticulocyte counts can be obtained. In general, when neonates are being evaluated, the absolute reticulocyte count is the most helpful (Christensen et al., 2016b).

RBC morphology is quite heterogeneous in preterm and term infants as compared with adults. Irregularly shaped cells such as poikilocytes, acanthocytes, schizocytes, and burr cells are common in the blood smears of neonates. This reflects developmental changes in cell membrane deformability and flexibility. The neonatal RBC has a life span of approximately 70 to 80 days as compared with 120 days for the adult RBC.

Developmental Changes in the Regulation of Erythropoiesis

The principal growth factor that regulates erythropoiesis is Epo. This 30.4-kDa glycoprotein contains 165 amino acids and is extensively glycosylated, with 40% carbohydrate content. Epo maintains RBC production during fetal, neonatal, and adult life by inhibiting apoptosis of erythroid progenitors and by stimulating their proliferation and differentiation into normoblasts (Jelkmann, 1992). Since very little Epo crosses the placenta, the Epo concentrations measured in the fetus reflect fetal synthesis (Widness et al., 1991; Eichhorn et al., 1993). Epo production begins early in fetal life, and Epo has been identified in extraembryonic coelomic fluid and amniotic fluid (Campbell et al., 1992). The primary site of Epo production during fetal life is the liver, with transition to the kidney postnatally (Fahnenstich and Dame, 1996). This transition is mediated in part by expression of *GATA4* (Dame et al., 2004). Production of Epo is stimulated by hypoxia via hypoxia-inducible factor (HIF) 1 and 2 pathways (Dioum et al., 2009; Fisher et al., 2009; Lam et al., 2009; Semenza, 2009; Webb et al., 2009). HIF is a DNA-binding complex composed of two subunits: HIF-1 β , which is not oxygen responsive and is constitutively expressed, and either HIF-1 α or HIF-2 α , which are highly oxygen sensitive. The HIF complex is, in turn, regulated by prolyl hydroxylase domain enzymes 1–3 (Weidemann and Johnson, 2009). Elevated Epo concentrations (up to 8000 mU/mL) have been reported in pathologic states such as fetal hypoxia, anemia, and placental insufficiency and in infants of diabetic mothers (Teramo and Widness, 2009).

During fetal development, circulating Epo concentrations range from 4 mU/mL at 16 weeks of gestation to 40 mU/mL at term (Forestier et al., 1991; Fahnenstich et al., 1996). An unhealthy intrauterine environment can result in increased Epo production, reflecting fetal hypoxemia (Halmesmaki et al., 1990; Ruth et al., 1990). In healthy term infants, serum Epo concentrations decrease after birth to reach a nadir between the fourth and sixth week of age (Ruth et al., 1990). By 10 to 12 weeks, they reach adult

concentrations (approximately 15 mU/mL) (Kling et al., 1996). These changes in Epo concentrations are consistent with the changes in hemoglobin and hematocrit seen following term birth (physiologic anemia). In premature infants the anemia is more severe and persists longer, leading to anemia of prematurity. Epo concentrations in these infants are inappropriately low, forming the rationale for recombinant human Epo therapy.

Ontogeny, Organization, and Structure of Hemoglobins

Hemoglobin is a tetrameric molecule comprising two pairs of polypeptide subunits. As development proceeds, various hemoglobins are constructed by a combination of two α -like globins (ζ or α) with two β -like globins (ϵ , γ , δ , or β) to form hemoglobin tetramers. These tetramers include the embryonic hemoglobins, hemoglobin Gower 1 ($\zeta_2\epsilon_2$), hemoglobin Gower 2 ($\alpha_2\epsilon_2$), and hemoglobin Portland 1 ($\zeta_2\gamma_2$), fetal hemoglobin (hemoglobin F) ($\alpha_2\gamma_2$), and the adult hemoglobins A ($\alpha_2\beta_2$) and A₂ ($\alpha_2\delta_2$). Their expression and proportion depend on gestational age but can be modified by external mechanisms. The basic function of the various hemoglobins is similar, but their oxygen affinity differs. As the hemoglobins switch from embryonic to fetal to adult forms, oxygen affinity decreases. Thus the switch from embryonic to fetal to adult hemoglobin synthesis is a major mechanism by which the developing fetus adapts from the relatively hypoxic intrauterine environment to the relatively oxygen-rich extrauterine environment (Dzierzak and Phillipsen, 2013).

Changes in Hemoglobin Synthesis With Development

The genes within the α -globin and β -globin families are expressed according to a strict ontogenetic schedule, and the quantitative expression of the genes from each of these families is strictly balanced and coordinated (Bard, 2000). Hemoglobin synthesis begins around 14 days after conception, with synthesis of ζ -globin and ϵ -globin chains. These are replaced by the synthesis of α -globin and γ -globin chains by the fifth to seventh week of gestation (hemoglobin Gower 2, hemoglobin Portland 1, and hemoglobin F become predominant) (Gale et al., 1979). By 12 weeks of gestation, hemoglobin F ($\alpha_2\gamma_2$) accounts for almost all of the hemoglobin produced (Cividalli et al., 1974). After the 20th week of gestation, no ϵ -globin chains are produced, but the production of the ζ -globin chains can persist through the last trimester in pathologic conditions such as homozygous α -thalassemia. Expression of the γ -globin gene peaks during midgestation and declines rapidly during the last month of fetal gestation. β -Globin synthesis, required for hemoglobin A, starts at the sixth week of gestation, increasing as γ -globin synthesis declines, a transition that continues to the sixth month of life (Kazazian and Woodhead, 1973). Thus hemoglobin A synthesis quantitatively increases first after the 30th week of gestation. At the end of the last trimester a rapid switch from the synthesis of fetal hemoglobin to adult hemoglobin occurs, falling from 85% at 34 weeks of gestation to 60%–80% at birth (Peri et al., 1998). The synthesis of δ -globin chains, required for hemoglobin A₂ ($\alpha_2\delta_2$), begins at the 34th to 35th week of gestation. After birth, a rapid increase in hemoglobin A and hemoglobin A₂ synthesis occurs.

Red Blood Cell Transfusion

RBCs can be transfused to anemic patients to simultaneously increase the recipient's blood volume and RBC content, thereby increasing oxygen-carrying capacity. The technical ability to store blood for future transfusion was developed in the early 1900s

(Rous and Turner, 1916). In the early years, RBCs were kept viable in a citrate and glucose solution, but current solutions make it possible to store cells for up to 42 days in solutions such as citrate–phosphate–dextrose, citrate–phosphate–dextrose–adenine, and various additive solutions, which may contain additional dextrose, mannitol, and adenine (Nemkov et al., 2016). The hematocrit of “packed RBCs” typically ranges from 55% to 80%. During storage RBCs undergo metabolic and structural changes. 2,3-DGP, antioxidant, and ATP contents decrease, glycolysis decreases, osmotic fragility increases, and deformability decreases (Matthews et al., 2015). ATP-dependent membrane pumps become dysfunctional, and extracellular potassium content increases at a rate of 1 milliequivalent per day, which can be dangerous when large volumes are transfused quickly. Oxidative damage occurs in lipids and proteins during storage and irradiation (Remy et al., 2015). Proinflammatory compounds accumulate during storage of blood, particularly if it is not leukoreduced. After an RBC transfusion, the mean potential life span of the RBC is 85 days, with a mean half-life of 43 ± 11 days (Strauss et al., 2004).

The risks of RBC transfusion may be due to the storage process, the transfusion itself, and the association with oxidative damage. Because of the storage process and increasing age of the stored blood, RBC transfusion exposes the recipient to high levels of potassium, glucose, hydrogen, and lactic acid; the clinical significance depends on the age of the blood and the volume and speed of transfusion (Remy et al., 2015). Although rare, transfusion-transmitted bacterial infections can occur because of bacterial contamination of stored blood (Niu et al., 2006). Other risks of RBC transfusion include viral infections, transfusion-related acute lung injury, and graft-versus-host reaction (Lieberman et al., 2014). Multiple RBC transfusions in the absence of significant phlebotomy-related loss may also put the patient at risk of iron overload and oxidative injury (Park and Kim, 2015). There is 200 mg of iron in a 420-mL unit of whole blood, which is then processed into 250-mL units of packed RBCs (Porter, 2001), so a unit of blood with a hematocrit of 60% has an iron content of 0.7 mg/mL, which becomes available as the cells turn over. There is increased unbound iron in stored blood, which may increase the amount of reactive oxygen species (Hirano et al., 2001). In retrospective and observational studies, increased numbers of RBC transfusions have been associated with retinopathy of prematurity (Dani et al., 2001), bronchopulmonary dysplasia, necrotizing enterocolitis, and diuretic use (Valieva et al., 2009).

Optimal hematocrit values and indications for transfusions in infants in the neonatal intensive care unit (NICU) remain controversial. In the past, infants were transfused if the hematocrit fell below 40%. Because of the risk of transfusions and lack of evidence for benefit, more restrictive transfusion guidelines have been proposed (dos Santos et al., 2011). Most studies comparing restrictive with liberal transfusion practices in premature infants have not demonstrated a substantial and lasting benefit to maintaining higher hemoglobin levels (Bell et al., 2005; Kirpalani et al., 2006). In one study, neurodevelopmental outcome at school age was worse with liberal NICU transfusion practice (Nopoulos et al., 2011). Currently, there is no reliable marker to identify the need for transfusions in neonates, although the following have been studied: clinical indicators (Wardle and Weindling, 2001), lactic acid concentration (Wardle and Weindling, 2001; Takahashi et al., 2009), echocardiographic findings (Alkalay et al., 2003), and near infrared spectroscopic monitoring of cerebral and visceral oxygenation (Sandal et al., 2014).

Delayed clamping of the umbilical cord at birth, for 60 to 90 seconds, is a safe and effective means of increasing the baseline hematocrit of preterm neonates (Brocato et al., 2016). Mounting evidence indicates that cord milking or stripping, a more rapid means of accomplishing a placental/cord blood transfusion at birth, is equally safe and effective (Christensen et al., 2014; Katheria et al., 2015). Current practices for transfusion avoidance in the NICU include either delayed cord clamping or cord milking, plus efforts to reduce phlebotomy-related losses. The latter includes drawing all the blood needed for laboratory tests at birth using otherwise discarded fetal blood in the umbilical cord and thereby not drawing blood from small preterm infants on admission to the NICU (Henry et al., 2015b). An additional means of avoiding transfusions is to use erythropoiesis-stimulating agents, Epo, or long-acting darbepoetin. These can keep hemoglobin levels higher than otherwise, reduce transfusion requirements, and perhaps lead to better neurodevelopmental outcomes (Ohls et al., 2013, 2014, 2015, 2016).

Bilirubin Metabolism

The primary source of bilirubin in the fetus and neonate is metabolism of heme derived from hemoglobin in circulating erythrocytes. The rate-limiting step in heme breakdown is the formation of biliverdin, a process controlled by heme oxygenase (Rodgers and Stevenson, 1990). After heme breakdown the iron is recycled, carbon monoxide is liberated and exhaled, and biliverdin is reduced to bilirubin IX α by biliverdin reductase. In utero, unconjugated bilirubin is processed by the mother after placental transfer. Postnatally, exhaled carbon monoxide can be quantified to assess the heme breakdown rate (Christensen et al., 2016a). Unconjugated bilirubin is lipophilic and tightly bound to circulating albumin. The conjugation of bilirubin results in a relatively polar, water-soluble molecule, bilirubin diglucuronide, which can be excreted. This process occurs in the liver and is dependent on ligandin, a transfer protein, and the enzyme uridine diphosphoglucuronyl transferase. The conjugating ability of the fetus and newborn is impaired relative to that of older individuals because of reduced transferase activity and low levels of uridine diphosphoglucuronic acid (Dennerly et al., 2001).

Developmental Aspects of Megakaryocytopoiesis

Platelets are small (7.5 fL) anucleated fragments of megakaryocytes that circulate as relatively smooth disks when unactivated. The normal circulating life span of a platelet is 10 days. Platelets provide hemostasis when a breach of the vascular endothelial lining occurs and they activate and adhere to the exposed subendothelium. Activated platelets generate mediators, including the potent vasoconstrictor thromboxane A₂ and adenosine diphosphate, both of which further contribute to hemostatic plug formation (Gremmel et al., 2016).

Sites of Megakaryocyte Production

Megakaryocytopoiesis is the process by which megakaryocytes, and ultimately platelets, develop. As with erythropoiesis, the sites of megakaryocytopoiesis change during embryonic and fetal development. In mouse development, megakaryocytes are found in the early yolk sac (McGrath and Palis, 2005). These cells, when

cultured in the presence of stem cell factor, IL-3, IL-6, Epo, TPO, and granulocyte colony-stimulating factor (G-CSF) produce not only BFU-E cells but also megakaryocyte colonies. Megakaryocyte progenitors share a common progenitor with primitive hematopoietic cells (McGrath and Palis, 2005). In humans, electron micrograph studies have shown megakaryocytes present in the liver and circulatory system as early as 8 weeks after conception (Hesseldahl and Falck-Larsen, 1971).

Megakaryocyte Precursors

Megakaryocytopoiesis begins with the pluripotent HSCs, which give rise to myeloid progenitor cells (colony-forming unit–spleen cells), then burst-forming unit–megakaryocyte cells, followed by colony-forming unit–megakaryocyte cells (see Fig. 78.1). Further maturation brings these small mononuclear cells that are largely indistinguishable from monocytes to large polyploid cells, which are easily recognized on the basis of their phenotype. The process of megakaryocyte differentiation has been separated into four stages. Stage I cells, or megakaryoblasts, are the smallest and most immature. As cells mature through stage II (promegakaryocytes), stage III (granular megakaryocytes), and stage IV (mature megakaryocytes), the nucleus becomes multilobed, the cytoplasm becomes increasingly eosinophilic by Wright–Giemsa staining, and cellular size increases from 6–24 μm up to 50 μm . The presence of granules increases steadily until in the mature cells they become organized into “platelet fields.” Unlike in other cell lines, as the nucleus of megakaryocytes matures, it undergoes endomitosis or endoreduplication, a process by which cell ploidy is increased in the absence of cell division. Megakaryocytes from adults typically have a modal ploidy of 16N, while comparable samples from preterm or term infants have a significantly lower ploidy of less than 8N (Slayton et al., 2005). Megakaryocytes from newborns are also typically smaller than those in adults, although they manifest features of mature megakaryocytes (Fuchs, et al., 2012). Adult-size megakaryocytes appear by 2 years of age. Typically, smaller cells with lower ploidy produce fewer platelets than do larger cells with higher ploidy. Despite this, the platelet counts of fetuses are only slightly lower than those of adults (Wiedmeier et al., 2009).

Control of Megakaryocytopoiesis

Platelets serve the primary function of hemostasis but also participate in antimicrobial defense and tissue repair (Grozovsky et al., 2015). Multiple cytokines participate in the process of megakaryocytopoiesis; however, TPO is the principal one. Stem cell factor, IL-3, and IL-6 increase ploidy and the size of megakaryocytes. IL-11 also stimulates the proliferation of megakaryocyte progenitors and induces megakaryocyte maturation, while still other growth factors such as Epo, stem cell factor, GM-CSF, IL-1, basic fibroblast growth factor, platelet-derived growth factor, and interferon- γ have a less clearly defined role. Some cytokines inhibit thrombopoiesis, including transforming growth factor β and platelet factor 4 (Gewirtz et al., 1995). The magnitude of the influence of these growth factors changes with development.

Thrombopoietin

The presence of a growth factor regulating platelet formation was hypothesized in the 1950s but was not realized until 1994 when the protein was isolated by Kaushansky (2015). TPO is composed of 332 amino acids and contains two domains. The amino terminal is the active domain (153 amino acids) and bears marked homology

to Epo. TPO is produced primarily by the liver, although other tissues express small amounts. It acts as a potent stimulator of all stages of megakaryocyte development by binding to its specific cell-surface receptor, c-myeloproliferative leukemia (MPL). In TPO- and c-MPL-knockout models, platelet production is 10%–15% of that of controls, confirming that TPO is the primary regulator of platelet production but also indicating that alternative pathways exist for megakaryocytopoiesis. TPO is bound to the surface of platelets by its receptor, thereby reducing megakaryocyte exposure to the hormone (Kaushansky, 2015). Serum TPO concentrations tend to be lower in preterm infants than in older infants and children, and the TPO response to thrombocytopenia is less robust as gestational age decreases. This is counterbalanced by an increased sensitivity of megakaryocyte precursors to TPO (Liu and Sola, 2011).

Developmental Changes in Platelet Count

Fetal platelet counts increase with gestation. At 15 weeks the average platelet count is 187,000/ μL , increasing to 274,000/ μL at term. Overall, preterm infants have slightly lower platelet counts than do adults with a broader range of normal (100,000/ μL –450,000/ μL) (Wiedmeier et al., 2009; Henry and Christensen, 2015a).

Platelet Transfusions

Clinical practice regarding platelet transfusion is inconsistent since no evidence-based guidelines are available (Cremer et al., 2016). In a 2005 Web-based survey of neonatologists in the United States and Canada, wide variations in practice were noted, with platelet transfusions frequently administered to nonbleeding neonates with platelet counts greater than 50,000/ μL . This practice was particularly common during indomethacin treatment, before or after procedures or operations, or after diagnosis of intraventricular hemorrhages (Josephson et al., 2009). This is concerning because several studies show a correlation between the number of platelet transfusions received by hospitalized neonates and mortality rate (Garcia et al., 2001; Baer et al., 2007). In a study of 1600 thrombocytopenic NICU patients, those who received platelet transfusions had higher mortality rates: 2% for those with no transfusions, 11% for those with 1 or 2 transfusions, 35% for those with more than 10 transfusions, and 50% with 20 or more transfusions (Baer et al., 2007). This was partially due to the underlying illness that required the infant to be transfused. However, since transfusion practices differ so widely, some of the increased mortality could statistically be ascribed to harmful effects of multiple platelet transfusions. In an attempt to create a reasonable, yet safe approach to platelet transfusions, two guidelines were prospectively compared: one based on platelet count and the other based on platelet mass (platelet count times mean platelet volume). Fewer patients were transfused when platelet mass was used as a transfusion trigger (Gerday et al., 2009). Roberts et al. (2008) recommended that prophylactic transfusions of platelets be avoided after the first week of life unless the platelet count falls below 30,000/ μL . During the first week of life, they recommend a transfusion trigger of 50,000/ μL for preterm infants. For patients with platelet counts greater than 50,000/ μL , transfusions should be reserved for those with active serious bleeding. Another controversy concerns the preparation of platelets: single donor, multiple donor, single unit, or volume-reduced multiple unit preparations. In general, 10- to 20-mL single donor platelets per kilogram should raise the platelet count by more than 100,000/ μL . In the absence of consumption, some of the donor

platelets should remain in the recipient's circulation for 1 week. Use of volume-reduced or pooled platelets should be avoided because processing results in platelet activation and decreased function.

Developmental Aspects of Granulocytopoiesis

Early hematopoiesis is characterized almost exclusively by erythropoiesis, although a small number of macrophages are produced in the yolk sac. After circulation begins in the fourth to fifth week of gestation, macrophages appear in the liver, brain, and lungs. During the fifth week, hematopoiesis begins in the liver, and the first hematopoietic cells to appear are macrophages (Kelemen and Janossa, 1980). Whether Kupffer cells originate in the yolk sac and migrate to the liver or arise de novo in the liver is unknown. The marrow space begins to develop around the eighth week after conception, and as occurs in the liver, the first hematopoietic cells to appear in the bones are phagocytes (Kelemen and Janossa, 1980; Slayton et al., 1998b). These phagocytic osteoclasts seem to core out the marrow space. When hematopoiesis is established in the marrow at 10 to 11 weeks after conception, primarily neutrophils are produced, in contrast to the liver, where primarily macrophages are present (Slayton et al., 1998a, 1998b).

The thymus appears around 8 weeks after conception. T-cell progenitors are thought to migrate from the fetal liver to the thymus at 8 to 9 weeks after conception (Haynes et al., 1989), and by the 10th week, lymphoid cells constitute 95% of this organ, with granulocyte precursors and macrophages making up the remainder. B-cell precursors first appear in the omentum and the fetal liver at 8 weeks after conception. B-cell production in the omentum occurs transiently from 8 to 12 weeks (Solvason and Kearney, 1992), while production continues in the fetal liver. Regulatory T cells are found in the thymus and secondary lymphatic organs in the early second trimester and are proposed to be involved in self-reactivity and immune tolerance (Cupedo et al., 2005; Izcue and Powrie, 2005).

The spleen is an important secondary lymphatic organ in humans. The human spleen does not have intrinsic granulocytopoiesis and erythropoiesis activities or produce hematopoietic growth factors (Calhoun et al., 1996), and lymphocytes appear to migrate there through fetal blood. Lymphocytes begin to appear in the spleen around 11 weeks after conception. By the 22nd week, 70% of the cells are lymphocytes.

Overview of Hematopoietic Cytokines

Hematopoietic growth factors can be classified into two groups: those responsible for the regulation of myeloid and erythroid growth and differentiation, called *colony-stimulating factors*, and those concerned with immunity, called *lymphokines*. Once sequenced, lymphokines are assigned IL numbers. There is a great deal of

functional overlap between hematopoietic growth factors (redundancy), and each growth factor has a multiplicity of biologic actions (pleiotropy). Thus more than one cytokine controls cells in any cell lineage, and most factors affect cells in more than one lineage (Vaidya and Kale, 2015).

Epo, GM-CSF, and G-CSF belong to a family of hematopoietic cytokines that share a tertiary structure and function by binding to specific cell-surface receptors. Specific ligand binding results in allosteric changes in the receptor molecules, which, depending on the type of receptor, results either in protein kinase activation, as with macrophage colony-stimulating factor (Bourette and Rohrschneider, 2000), or in a cascade of intracellular signaling via the Janus kinase 2 mechanism, as is characterized by Epo (Kuhrt and Wojchowski, 2015).

Many of the hematopoietic cytokines were discovered on the basis of their growth-promoting effects on hematopoietic cells or their specific immune functions. It was initially assumed that their effects were specific to the hematopoietic system. This view was incomplete. Functional receptors are expressed by other nonhematopoietic cells, with clear nonhematopoietic functions as reviewed by Li et al. (2015) and Juul and Pet (2015). For example, both glia and neurons produce many of the cytokines once thought to be restricted to the hematopoietic system. Furthermore, they express receptors for these peptides, indicating the capability of both paracrine and autocrine interaction. Epo and G-CSF are both available in recombinant form and are approved by the US Food and Drug Administration for clinical use.

Neonatal Bleeding and Thrombotic Disorders

MATTHEW A. SAXONHOUSE

KEY POINTS

- Acquired or inherited coagulation disorders should be considered in any neonate that suffers significant hemorrhage.
- Treatment for specific coagulation disorders should be provided in consultation with pediatric hematology and based on the most current guidelines.
- Thromboembolism (TE) is a significant problem affecting both term and preterm neonates.
- Most neonates that experience a significant TE event have acquired risk factors and/or a prothrombotic disorder.
- Proper imaging is essential for accurately identifying neonatal TE events.
- The use of central venous/arterial catheters significantly increases a neonate's risk for thrombosis.
- Recommendations for treatment for neonatal TE events are based on expert opinion and data from case studies/series.
- Care for neonates with coagulation disorders or significant TE events should occur in a tertiary referral center that has appropriate subspecialty support.

Neonatal bleeding and thrombotic disorders may present a diagnostic challenge to the physician. Excess and/or deficiencies of certain coagulation/anticoagulation proteins coupled with multiple acquired and/or prothrombotic risk factors and/or thrombocytopenia can result in a hemorrhagic or thromboembolic (TE) emergency. The timely diagnosis of a congenital hemorrhagic disorder can potentially avoid significant long-term sequelae, while the lack of randomized clinical trials addressing the management of neonatal thromboses can leave a neonatologist guessing on what the optimum treatment strategy should be. In this chapter, we first review the neonatal hemostatic system. Neonatal hemorrhagic disorders are presented with a discussion of current treatment options. Congenital and acquired risk factors and common sites for neonatal thromboses are reviewed. Finally, suggested evaluations for neonates with TE emergencies as well as the latest treatment options are presented.

The Neonatal Hemostatic System

Blood vessel injury caused by damaged endothelium leads to bleeding. If this bleeding is not curtailed, pathologic hemorrhage

will occur. Hemostasis refers to the process in which bleeding is controlled at the site of damaged endothelium (Roberts et al., 2006). The process of hemostasis involves the interaction between endothelium, subendothelium, platelets, circulating cells, and plasma proteins. Blood vessel injury leads to an immediate, local response of both plasma and cellular components. Thrombosis is confined to the area of injury, leading to eventual tissue repair. A model of hemostasis combining the vascular, platelet, and plasma phases is presented in Video 79.1. The end result is a localized, firm thrombosis, leading to cessation of bleeding. The thrombosis then serves as a scaffold for tissue repair, leading to complete restoration of the endothelial lining (Young, 2015). Fibrinolysis, as demonstrated in Video 79.2, must occur for blood vessel repair and return of blood flow.

Hemostatic processes are regulated by natural anticoagulants (Video 79.3), whose job is to contain these processes at the site of injury and to prevent these reactions from becoming systemic and pathologic (Young, 2015). Deficiencies in natural anticoagulation proteins may lead to the formation of pathologic thromboses during the neonatal period, and these disorders are described later. The complex interaction of the hemostatic, fibrinolytic, and anticoagulant components of the hemostatic system results in a well-balanced machine that allows for hemostasis to occur at the site of injury and for fibrinolysis to follow, facilitating a localized tissue repair process.

Developmental Hemostasis

The neonatal hemostatic system differs significantly from that of older children and adults (Will, 2015). The concentrations of the procoagulant, anticoagulant, and fibrinolytic proteins, compared with adults, are shown in Table 79.1. Essentially all of the procoagulant proteins, except for fibrinogen, factors V and VIII, and von Willebrand factor (vWF), are lower. These lower levels are balanced by lower levels of anticoagulant proteins, except for alpha2-macroglobulin, which is the only anticoagulant protein that is elevated during the neonatal period. All of the fibrinolytic proteins are reduced. These differences place a neonate in a “relative” prothrombotic state, but other factors balance the system and prevent a term or “well” premature neonate from experiencing spontaneous thrombosis. However, many acquired (Table 79.2) and/or prothrombotic risk factors may disrupt this balance, shifting the neonate into a prothrombotic state.

TABLE 79.1 Neonatal Coagulation/Anticoagulation/Fibrinolytic Protein Levels Compared With Adult Levels

| | Protein Levels Elevated Compared With Adult Values | Protein Levels Decreased Compared With Adult Values |
|---------------|---|--|
| Procoagulant | Fibrinogen Factor V ^a Factor VIII vWF | ^b Factors II, VII, IX, X, XI, XII, XIII Prekallikrein High-molecular-weight kininogen |
| Anticoagulant | Alpha2-macroglobulin | Antithrombin III Heparin cofactor II Protein C Protein S |
| Fibrinolytic | Tissue plasminogen activator Plasminogen activator inhibitor | Plasminogen α_2 -antiplasmin |

^aFactor V levels are low on day of life 1 but reach adult values within days after birth (Will, 2015).

^bLevels are 50% of adult values (Will, 2015).

TABLE 79.3 Laboratory Diagnostic Criterion for the Bleeding Newborn^a

| Disorder | PT | APTT | Platelets | Fibrinogen |
|------------------------------------|--------|-----------------------|-----------|------------|
| Hemophilia A | Normal | ↑↑↑ | Normal | Normal |
| Hemophilia B | Normal | ↑↑↑ | Normal | Normal |
| Hemophilia C | Normal | ↑↑ | Normal | Normal |
| Factor XIII deficiency | Normal | Normal | Normal | Normal |
| Factor II, V, and X deficiency | ↑↑ | ↑↑ | Normal | Normal |
| Hemorrhagic disease of the newborn | ↑↑↑ | Normal/↑ ^b | Normal | Normal |
| DIC ^c | ↑↑↑ | ↑↑↑ | Low | Low |
| Liver disease ^c | ↑↑↑ | ↑↑↑ | Low | Low |
| vWD | Normal | Normal/↑ | Normal | Normal |
| Hypofibrinogenemia | ↑↑↑ | ↑↑↑ | Normal | Low |
| Dysfibrinogenemia | ↑↑↑ | ↑↑↑ | Normal | Normal/Low |

^aA complete blood count and coagulation screening test should be performed for any bleeding infant.

^bAPTT values may be prolonged but not as severe as the elevated PT value.

^cTo differentiate between DIC and liver disease, a factor VIII value should be obtained. Factor VIII values will be normal in infants with liver disease but low in infants with DIC.

APTT, Activated partial thromboplastin time(s); DIC, disseminated intravascular coagulation; PT, prothrombin time(s); vWD, von Willebrand disease.

References (Campbell and Bolton-Maggs, 2015; Young, 2015; Jaffray et al., 2016).

The exact reasons for the differences in the fetal and neonatal hemostatic system, compared with adults, are unclear but supported by recent theories. The lower levels of antithrombin III (ATIII) are balanced by elevated concentrations of alpha2-macroglobulin, allowing for unrestricted angiogenesis during intense growth while maintaining an effective anticoagulant pathway (Monagle et al., 2006; Monagle and Massicotte, 2011). Lower levels of vitamin K during fetal growth may reduce the synthesis of osteocalcin, preventing premature fetal cartilage maturation (Booth, 1997).

Despite having a balanced hemostatic system at birth, neonatal prothrombin time (PT) and activated partial thromboplastin time (APTT) are elevated when compared with adults. Elevated tissue factor (TF) in neonates compensates for the lower levels of tissue factor pathway inhibitor (TFPI) and ATIII. Some aspects of decreased platelet aggregation in neonates are compensated for with higher levels of vWF and factor VIII (FVIII). Therefore despite the lower levels of coagulation proteins, neonates are able to form effective thromboses.

The neonatal hemostatic system undergoes numerous changes over the first 6 months of life, and many of the lower protein levels reach adult values during this time period.

Bleeding Disorders in the Neonate

When a neonatologist is faced with either an actively bleeding infant or one that has suffered a significant hemorrhage, acquired or inherited coagulation defects must be considered, especially if the neonate has a normal platelet count. Laboratory diagnostic criteria for the bleeding newborn are shown in Table 79.3. Inherited

TABLE 79.4 Acquired and Inherited Bleeding Disorders in Neonates

| Inherited | Classification | Symptoms |
|--|--|--|
| Hemophilia A (FVIII) Hemophilia B (FIX) | Severe (<1%) Moderate (1–5%) Mild (>40%) | Bleeding after circumcision and/or blood draws, ICH, extracranial hemorrhage, excessive bruising, muscle hematomas, bleeding after surgery |
| Fibrinogen deficiency | Decreased levels (heterozygote): hypofibrinogenemia Absent levels (homozygote): afibrinogenemia Dysfunctional Dysfibrinogenemia | Prolonged bleeding from umbilical stump, bleeding after circumcision, ICH, or mucocutaneous bleeding |
| Factor II (prothrombin) Factor V | Commonly associated with congenital anomalies, particularly cardiac defects | Mucocutaneous bleeding, ICH, prolonged bleeding from umbilical stump, bleeding after procedures |
| Factor VII Factor X Factor XI | Levels do not correlate well with bleeding phenotype | |
| Factor XIII | Levels do not correlate well with bleeding phenotype | Umbilical cord stump bleeding, ICH, bleeding after procedures |
| Acquired | Classification | Symptoms |
| DIC Liver disease | | Prolonged bleeding after venipuncture/heel sticks, jaundice, pulmonary hemorrhage |
| Vitamin K deficiency | Early <24 hours Classical 1–7 days Late ≥2 weeks | Cephalohematoma, umbilical stump bleeding, ICH GI bleeding, umbilical stump bleeding, mucocutaneous, circumcision, ICH ICH, mucocutaneous, GI bleeding |

DIC, Disseminated intravascular coagulation; *FVIII*, factor VIII; *FIX*, factor IX; *GI*, gastrointestinal; *ICH*, intracranial hemorrhage.

and acquired coagulation defects and the most common symptoms associated with their presentation in the neonate are shown in [Table 79.4](#). It is important to obtain a detailed family and delivery history for any neonate experiencing significant bleeding, as certain clues may be presented, allowing the clinician to perform a focused approach.

Laboratory Investigation

The first approach (initial screen) to any neonate with a suspected bleeding disorder should be a complete blood count (CBC) and coagulation screen (PT, APTT, and fibrinogen). More specific testing should then be performed to make the correct diagnosis. It is important for the neonatologist to remember that the method of sample collection may affect sample results: for example, heel-stick samples may result in platelet clumping, which will produce a falsely low platelet count and should never be used for coagulation screening. Elevated hematocrit levels greater than 55% may result in prolonged diluted coagulation times. In addition, the collection of blood samples through heparinized arterial or venous lines will prolong the APTT, unless the specimen has the heparin absorbed and/or adequate blood is removed from the line before the sample collection in order to clear heparin from the line. When interpreting values from coagulation screening and more detailed testing, values should be interpreted using age-adjusted normal ranges based on gestational age and days of life; these are published elsewhere ([Andrew et al., 1987, 1988b, 1990](#)).

Hemophilia

The most common congenital bleeding disorders are hemophilia A (FVIII deficiency) and hemophilia B (factor IX deficiency), both being inherited as sex-linked recessive. The incidence of hemophilia A is 1 per 5000 males and for hemophilia B is 1 per 20,000 males ([Soucie et al., 1998](#)). Approximately one-third of cases will occur in the absence of a positive family history ([Chalmers, 2004b](#)). Heterozygous females may have mild hemophilia as a result of nonrandom X-chromosome inactivation ([Young, 2015](#)). The severity of hemophilia is determined by the type of mutation and the part of the protein that is affected ([Young, 2015](#)). With the absence of either FVIII or factor IX, there is reduced thrombin formation on the surface of activated platelets, resulting in a thrombosis with poor structural integrity that is more susceptible to fibrinolysis, and as a result, bleeding occurs. The lower the factor level, the greater the potential for more severe early onset bleeding. Approximately 70% of patients with hemophilia are diagnosed during the first month of life, with the mean age of patients with hemophilia having their first bleed by 28.5 days ([Conway and Hilgartner, 1994; Chalmers, 2004b](#)). The most common presentation of hemophilia in the neonate is excessive bleeding, either after circumcision or surgery. Further classifications of hemophilia A and B, based on factor activity level, and the types of bleeding that neonates may present with are shown in [Table 79.4](#).

Most symptomatic infants will have significant prolongation of their APTT; however, if the diagnosis is suspected, specific

TABLE 79.5 Treatment for Congenital/Acquired Bleeding Disorders

| Factor | Replacement Therapy |
|--------------------------------|---|
| Hemophilia A | Factor VIII concentrate |
| Hemophilia B | Factor IX concentrate |
| Fibrinogen | Fibrinogen concentrate FFP or cryoprecipitate if concentrate unavailable |
| Factor II | Prothrombin complex concentrate (if available) FFP if concentrate unavailable |
| Factor V | FFP |
| Factor VII | Recombinant factor VIIa or prothrombin complex concentrate (if available) |
| Factor X | Prothrombin complex concentrate (if available) FFP if concentrate unavailable |
| Factor XI | FFP |
| Factor XIII | Plasma derived and recombinant (only for A subunit deletions) FXIII concentrate Cryoprecipitate if concentrate unavailable |
| Early vitamin K deficiency | Parenteral vitamin K |
| Classical vitamin K deficiency | Prothrombin concentrates for active bleeding |
| Late vitamin K deficiency | |
| ^a DIC | FFP and cryoprecipitate, platelets |
| ^a Liver disease | Cryoprecipitate, FFP, prothrombin complex concentrates, platelets, vitamin K, recombinant factor VIIa |

^aTherapies for bleeding patients, not abnormal laboratory testing.

DIC, Disseminated intravascular coagulation; FFP, fresh frozen plasma; FXIII, factor XIII.

From Saxtonhouse MA, Manco-Johnson MJ. The evaluation and management of neonatal coagulation disorders. *Semin Perinatol*. 2009;33:56; with permission.

References (Campbell and Bolton-Maggs, 2015; Young, 2015; Jaffray et al., 2016).

factor levels should always be obtained. If there is a strong family history for hemophilia, factor levels may be screened from cord blood samples, but severity of disease should always be determined from samples obtained after the infant is born.

Because FVIII levels are increased during the neonatal period, the diagnosis of mild hemophilia A may be difficult, and confirmatory testing should be done at 6 to 12 months of age. In addition, lower levels of factor IX at birth may also make the diagnosis of mild hemophilia B difficult, and testing should also be repeated at 6 to 12 months of life. Treatment is replacement of the specific factor and should be done in consultation with pediatric hematology, as there are a number of factor concentrates that are commercially available for both FVIII and factor IX deficiency (Table 79.5) (Young, 2015). Many neonates do not require treatment during the neonatal period, as they may not manifest any bleeding symptoms. Adjuvant therapies for hemophilia (used only in conjunction with pediatric hematology), such as desmopressin, may increase factors to hemostatic levels, which can be useful for management of minor bleeding (Young, 2015). Fresh frozen plasma (FFP) should only be used in the instance of acute hemorrhage when confirmatory

testing is not yet available (Chalmers, 2004a; Kulkarni and Lusher, 2001).

von Willebrand Disease

The primary plasma protein required for platelet adhesion, vWF, also has a role in platelet aggregation and serves as the carrier for FVIII (Young, 2015). Absence, reduction, or abnormal function of vWF results in defects in platelet adhesion and aggregation, increasing one's risk for bleeding. The effectiveness of vWF as an adhesive protein relies on multimerization of the protein, resulting in very large molecules comprising what are known as high-molecular-weight multimers (Young, 2015). Neonates have higher plasma concentrations of vWF and an increased proportion of high-molecular-weight vWF multimers. As a result, presentation of von Willebrand disease (vWD) during the neonatal period is rare (Weinstein et al., 1989).

The spectrum of vWD consists of quantitative (types 1 and 3) or qualitative defects (types 2A, 2B, 2M, and 2N). Type 1 is due to reduced amounts of vWF resulting from either decreased production/secretion of vWF or increased clearance of circulating vWF (Young, 2015). Type 3 is caused by complete absence of vWF and is usually the result of severe gene mutations and has the highest potential for presentation during the neonatal period. Type 2A is caused by defects in multimerization that result in an absence of large and medium-sized multimers, affecting platelet adhesion (case reports in neonates). Type 2B is due to a mutation that leads to increased binding of the high-molecular-weight multimers to platelets, removing them from the available pool in the plasma (case reports in neonates). Type 2M is due to a mutation resulting in the inability of vWF to bind to platelets. Type 2N affects vWFs' ability to bind to FVIII and results in a reduction of circulating levels of FVIII (Donner et al., 1987; Sadler et al., 2006; Branchford and Di Paola, 2012; Ng et al., 2015). Acquired vWD syndrome is extremely rare and has been associated with Wilms tumor, congenital heart disease, and systemic lupus erythematosus (Young, 2015).

Suspicion for vWD in a neonate requires specialized testing. Coagulation testing may demonstrate an isolated prolonged APTT and prolongation of epinephrine and ADP closure times as measured by the PFA-100. Further testing would evaluate the levels of vWF (vWF antigen assay), platelet-binding function (ristocetin cofactor assay), and FVIII-binding function (FVIII activity) (Branchford and Di Paola, 2012; Ng et al., 2015). Assistance by a pediatric hematologist should occur if a diagnosis is suspected (Young, 2015).

The management of type 3 vWD should consist of factor replacement using an intermediate purity FVIII concentrate containing the high-molecular-weight multimers of vWF (Sadler et al., 2006; Ng et al., 2015). Desmopressin should be reserved for those patients with type 1 vWD but should only occur after consultation with a pediatric hematologist (Young, 2015).

Other Rare Inherited Coagulation Disorders

There are other rare factor deficiencies, inherited as autosomal recessive, in 1 in 500,000 to 1 in 2,000,000 live births, representing 3%–5% of all coagulation disorders (Acharya et al., 2004; Palla et al., 2015). A complete listing of the disorders and their potential symptoms are displayed in Table 79.4. Severe deficiencies of fibrinogen, factor VII, factor X, and factor XIII are the most likely (of the rare coagulation disorders) to present during the neonatal period. The majority of these deficiencies will present with an

abnormality in the coagulation screen (Table 79.3). Further testing for the specific abnormality will then confirm the diagnosis (Jaffray et al., 2016). The clinician must remember that newborn levels of many of these factors are lower to start with, and therefore diagnosis may be difficult and must be confirmed by 6 to 12 months of life. Treatment for the various deficiencies is shown in Table 79.5.

Factor XIII is composed of two subunits and cross-links with fibrin to stabilize clots. Low levels of factor XIII do not prolong the PT or APTT. Therefore any neonate with concerns for a coagulation disorder that has a normal platelet count, normal fibrinogen levels, and normal PT and APTT values should be screened for factor XIII deficiency via a quantitative assay. Treatment is shown in Table 79.5.

Acquired Coagulation Disorders

Vitamin K Deficiency

Vitamin K is found in leafy green vegetables as vitamin K₁ (phylloquinone) and is synthesized as vitamin K₂ in intestinal bacteria (Saxonhouse and Manco-Johnson, 2009). It is an essential cofactor for the γ -carboxylation process of factors II, VII, IX, and X and protein C and protein S (Jaffray et al., 2016). Insufficient bacterial colonization of the colon at birth, inadequate dietary intake in solely breastfed infants, and poor transfer across the placenta places neonates at risk for vitamin K deficiency bleeding (VKDB). The different forms and their clinical presentation are shown in Table 79.4. Treatment is shown in Table 79.5.

Early VKDB is due to maternal ingestion of oral anticoagulants, anticonvulsants, and antituberculosis agents. These agents cross the placenta and interfere with vitamin K metabolism. Classical VKDB occurs because of a physiologic deficiency in vitamin K at birth combined with a sole breast milk diet or inadequate feeding. Late VKDB presents in an infant that is either solely breastfed who receives an inadequate dose of vitamin K (none or one oral dose) or has an associated disease process that interferes with the absorption or supply of vitamin K such as diarrhea, cystic fibrosis, α_1 -antitrypsin deficiency, biliary atresia, hepatitis, and celiac disease. In the absence of vitamin K prophylaxis, the incidence of late VKDB is 4 to 10 per 100,000 births (Sutor, 1995). When intramuscular (IM) vitamin K prophylaxis is provided, the incidence of late VKDB decreases to 0.24 to 3.2 per 100,000 live births (Schulte et al., 2014).

If VKDB is suspected, coagulation screening should be performed and will usually demonstrate isolated prolongation of the PT, followed by prolongation of the APTT. The prolongation of the PT is usually out of proportion to the elevation of the APTT. Fibrinogen concentration and platelet counts will be normal. In addition, decreased concentrations of factors II, VII, IX, and X will occur. An alternative is to obtain an undercarboxylated or abnormal coagulation factor II measurement (Clarke and Shearer, 2007). This factor is released into the bloodstream in the very early stages of vitamin K deficiency, and it can be detected well before changes in the PT become manifest. The adoption of this single test in clinical practice may improve the early diagnosis of VKDB, resulting in decreased incidences of intracranial hemorrhage (ICH).

When presented with a patient with suspected VKDB, parenteral treatment (intravenous, IM, or subcutaneous injection) with vitamin K should immediately occur. Improvement of the PT and APTT 2 to 6 hours after the administration of parenteral vitamin K will confirm the diagnosis. However, if a patient suspected of having

VKDB presents with severe hemorrhage, additional therapy with prothrombin complex concentrates (contain all the vitamin K-dependent factors; not available at every institution) aimed at immediate correction of factor deficiencies should occur (Young, 2015).

Common practice in the United States is to provide all infants 1.0 mg (0.3 mg/kg for infants <1000 g and 0.5 mg for infants >1000 g but <32 weeks' gestation) of IM vitamin K on the first day of life (Saxonhouse and Manco-Johnson, 2009). This single dose has been found to prevent both classical and late VKDB, even in infants with cholestatic jaundice (American Academy of Pediatrics Committee on Fetus and Newborn, 2003; McNinch et al., 2007). The safety of IM vitamin K has been questioned because of the reported association between IM vitamin K administration in newborns and an increased incidence of childhood cancer (Golding et al., 1990, 1992). Further studies have concluded no association between IM vitamin K and childhood leukemia or other cancers (Ross and Davies, 2000). Further research has suggested a prenatal origin of childhood leukemia, further weakening the plausibility of a causal relationship between IM vitamin K and cancer (Wiemels et al., 1999).

Proper oral administration of vitamin K has been shown to have an efficacy similar to that of IM vitamin K in the prevention of early and classical VKDB (von Kries and Hanawa, 1993; Puckett and Offringa, 2000). However, cases of late VKDB began to increase and surveillance data from four countries revealed oral prophylaxis failures of 1.2 to 1.8 per 100,000 live births (Cornelissen et al., 1997), with higher rates of 2 to 4 per 100,000 cases when incomplete oral dosing was observed. More recent data have demonstrated that weekly or daily oral dosing of vitamin K protects almost all babies from VKDB, and late VKDB remains confined to breastfed infants who received no vitamin K or just one oral dose (Hansen et al., 2003; van Hasselt et al., 2008).

A more recent study evaluated the association of VKDB in breastfed infants with unrecognized biliary atresia and oral vs IM dosing of vitamin K (Witt et al., 2016). Of 91 breastfed infants diagnosed with biliary atresia, 25 received a 2-mg IM dose after birth compared with 55 and 11 infants receiving 25- μ g and 150- μ g oral daily dosing, respectively; 4% of the infants that received IM dosing experienced vitamin K deficiency bleeding compared with 82% (both groups) of the infants that received only oral dosing. More importantly, 0% of the infants who received IM dosing experienced ICH compared with 40% and 27%, respectively, in the oral dosing groups (Witt et al., 2016).

Disseminated Intravascular Coagulation

A complex process involving the activation and dysregulation of the coagulation and inflammatory systems, disseminated intravascular coagulation (DIC), results in massive thrombin generation with widespread fibrin deposition and consumption of coagulation proteins and platelets, ultimately leading to multiorgan damage (Chalmers, 2004b). DIC always occurs as a secondary event, and many perinatal and neonatal problems are associated with it. These include birth asphyxia, respiratory distress syndrome, meconium aspiration syndrome, infection, necrotizing enterocolitis, hypothermia, severe placental insufficiency, homozygous protein C/S deficiency, and thrombosis (Chalmers, 2004b).

The diagnosis of DIC is made in an ill neonate with supporting laboratory parameters (Table 79.3). The most important aspect of treatment for DIC is to treat the underlying disorder. However, once DIC is established, it can be difficult to control (Chalmers, 2004b). The focus of acute management in the neonate is to

support adequate hemostasis to reduce the risk of spontaneous hemorrhage. This is usually achieved with platelet transfusions, FFP, or cryoprecipitate (Williams et al., 2002). Another option is to inhibit the activation of the coagulation system using heparin. However, trials in neonates have not been conclusive, and the risk of bleeding may be increased (Gobel et al., 1980; Albisetti et al., 2005).

Liver Disease

Acute liver disease is rare in the neonatal population. Illnesses that can lead to acute liver failure include congenital heart disease with low cardiac output, birth asphyxia, extrahepatic biliary atresia, inborn errors of metabolism, hemophagocytic syndrome, and viral hepatitis. Mechanisms contributing to hemostatic abnormalities include decreased synthesis of coagulation factors, activation of the coagulation and fibrinolytic systems, poor clearance of activated hemostatic components, loss of coagulation proteins into ascitic fluid, thrombocytopenia, platelet dysfunction, and vitamin K deficiency (Albisetti et al., 2005). The diagnosis of acute liver disease in the neonate should include elevated liver enzymes, direct hyperbilirubinemia, prolonged PT and APTT, thrombocytopenia, elevated ammonia concentrations, decreased fibrinogen levels, and decreased concentrations of factors VII and V (Table 79.3). A normal FVIII concentration, reflecting extrahepatic synthesis, can help distinguish primary liver disease from DIC (Albisetti et al., 2005). Treatment, in addition to treating the underlying cause of liver disease (if able), includes prothrombin complex concentrates (if available; Young, 2015), cryoprecipitate (if fibrinogen is low), FFP, recombinant factor VIIa (for bleeding not responsive to platelets and plasma products), platelets, and vitamin K.

Neonatal Thrombosis

Epidemiology

Neonatal TE is becoming an increasingly recognized condition. The exact incidence of neonatal TE varies with the types of thromboses reported and how centers screened for them. Four registries have reported data on the epidemiology of neonatal TE: the German registry reported an incidence of 5.1 events per 100,000 live births (Nowak-Gottl et al., 1997b); the Canadian registry reported 2.4 clinically apparent events (excluding stroke) per 1000 neonatal intensive care unit (NICU) admissions (Schmidt and Andrew, 1995); the Dutch registry reported 0.07 events per 10,000 children for venous thrombosis (van Ommen et al., 2001); and the most recent reports from the Italian registry reported an incidence of 3.4 to 6.5 per 10,000 live births and 5.8 to 6.6 per 1000 NICU admissions for noncerebral systemic venous and arterial thrombotic events (Saracco et al., 2016). All four registries observed that thromboses occurred in both term and preterm infants, with the Italian registry reporting a higher incidence among preterm infants. The German, Canadian, and Dutch registries reported an equal incidence among males and females other than renal vein thrombosis, which affected more male neonates (Schmidt and Andrew, 1995; Nowak-Gottl et al., 1997b; van Ommen et al., 2001), while the Italian registry reported a higher incidence for all types of thromboses among male neonates (Saracco et al., 2016). These registries also demonstrated that the majority of venous thromboses in neonates are associated with central venous catheters (CVCs) (Schmidt and Zipursky, 1984; Nowak-Gottl et al., 1997b; Saracco et al., 2016; van Ommen et al., 2001). The recurrence

rate for neonatal TE remains low and ranges from 3.3% to 7% (Kurnik et al., 2003).

Risk Factors for Neonatal Thromboembolism

Hypercoagulability, disturbances in blood flow, and endothelial damage/disruption (Virchow triad) all pertain in some degree to neonates admitted to the NICU (Young, 2015). Therefore it is understandable as to why neonates have the highest rate of TE events among pediatric patients. As demonstrated in Table 79.1, neonates, particularly premature neonates, are deficient in the anticoagulant proteins, especially protein C and protein S. Prothrombotic disorders may also be present, shifting the neonate into a hypercoagulable state. Hypovolemic, septic, or cardiogenic shock may affect an ill neonate, resulting in hypotension and thus disrupting blood flow to vital organs. Polycythemia or certain cardiac lesions may also result in sluggish blood flow and/or hyperviscosity, increasing the risk for thrombosis. However, the presence of CVC and arterial catheters is by far the greatest acquired risk for the development of TE in neonates (Schmidt and Andrew, 1995; Nowak-Gottl et al., 1997b; van Ommen et al., 2001; Greenway et al., 2004; Beardsley, 2007). Insertion, infusion of hyperosmolar substances, and length of time that a catheter remains in place may disrupt the endothelium, increasing the risk for thrombosis. The effects of different types of catheter materials, catheter design, and lumen number have been evaluated, and these reviews have only demonstrated that fewer thrombotic complications were associated with end-hole umbilical arterial catheters (UACs) (Barrington, 2000a, 2000b, 2000c, 2000d). Risk factors that have been implicated in neonatal TE are shown in Table 79.2.

Prothrombotic Disorders: Pathophysiology and Their Role in Neonatal Thromboembolism

A genetic mutation resulting in the complete absence or severe deficiency of an inhibitor of hemostasis, the production of an inhibitor of hemostasis that has inadequate function despite normal levels, or an overproduction of a procoagulant protein or cofactor greatly increases a neonate's risk for TE. The more severe the mutation, the greater the risk for the development of severe thrombosis. Homozygous prothrombotic disorders, such as severe protein C, protein S, or ATIII deficiency, usually present in newborns with severe clinical manifestations, mainly purpura fulminans (Monagle et al., 2004). The debate that continues is how the inheritance of a heterozygous prothrombotic mutation increases a neonate's risk for symptomatic TE. Despite having a heterozygote prothrombotic mutation, a neonate may never experience a symptomatic TE event, thus demonstrating that the inheritance of a prothrombotic trait does not guarantee a symptomatic TE event. Other acquired risk factors (Table 79.2) are usually present. Prothrombotic disorders that have been associated with neonatal TE are shown in Box 79.1.

Neonatal registries have demonstrated that greater than 80% of neonates with symptomatic thromboses have acquired risk factors present (Table 79.2) (Schmidt and Andrew, 1995; Nowak-Gottl et al., 1997b; van Ommen et al., 2001; Saracco et al., 2016). Therefore it appears that the combination of acquired factors and the presence of a prothrombotic mutation may represent the perfect storm for neonatal TE. Registry data and other case studies have demonstrated that the majority of symptomatic neonatal TE events stem either from the association of multiple prothrombotic defects or the combination of prothrombotic defects and environmental or clinical conditions (Schmidt and Andrew, 1995; Nowak-Gottl

• BOX 79.1 Prothrombotic Disorders Implicated in the Development of Neonatal Thromboembolism

Factor V Leiden mutation (most common)
 Factor II *G20210A* gene mutation (1%–2% of Caucasians)
 Increased apolipoprotein(a)
 Methylene tetrahydrofolate reductase gene mutation (*MTHFR C677T*) genotype
 Hyperhomocysteinemia
 Protein C deficiency
 Protein S deficiency
 Antithrombin III deficiency
 Heparin cofactor II deficiency
 Dysfibrinogenemia
PAI-1 4g/5G gene mutation
 Increased levels of factors VIII, IX, XI, or fibrinogen
 Antiphospholipid antibodies (including anticardiolipin antibodies, lupus anticoagulant)
 Chromosome 2q
 Chromosome 2q13 deletion

References (Alioglu et al., 2006; Boffa and Lachassinne, 2007; Bucciarelli et al., 1999; Dahlback et al., 1996; Kenet et al., 2010; Nowak-Gottl et al., 1999b, 2003; Rosendaal, 2005; Saxonhouse and Burchfield, 2009).

et al., 1997a, 1997b, 2001; van Ommen et al., 2001; Khan et al., 1991). It is therefore currently recommended that pediatric patients, including neonates, with thrombosis (regardless of other acquired risk factors) be tested for prothrombotic traits (Box 79.1) (Manco-Johnson et al., 2002). A more detailed laboratory approach based on type of thrombosis and acquired risk factors is presented later.

The most common prothrombotic disorder is the factor V Leiden mutation, which reduces the inactivation of activated factor V by its regulator, activated protein C (Zoller et al., 2014). The presence of the prothrombin 20210 mutation has the potential to increase circulating concentrations of prothrombin by 15%–30% (Poort et al., 1996; Junker et al., 1999). The exact role regarding mutations in the methylenetetrahydrofolate reductase (*MTHFR*) enzyme and risk for neonatal TE remains unclear (Couto et al., 2004). The mutation results in a defect in the remethylation of homocysteine into methionine, with the end result being hyperhomocysteinemia. Increased levels of homocysteine have been speculated as an increased risk for premature vascular disease and arterial thrombosis (Eldibany and Caprini, 2007; Khan et al., 1991). However, most studies have associated an increased risk for thrombosis because of elevated homocysteine levels (kidney damage) and not with the genetic mutation. Thus the *MTHFR* gene mutation and the risk of neonatal arterial thrombosis remain controversial (Rook et al., 2005; Brenner, 2006).

The activated protein C system, consisting of protein C plus protein S and factor V as cofactors, cleaves and inactivates factors V and VIII. Mutations that affect the quantity or quality of these proteins may contribute to an increase in neonatal venous thrombosis. ATIII, when bound to heparin sulfate, inhibits thrombin and activated factors IX, X, and XI. Mutations may result in deficiencies in ATIII production, increasing thrombosis risk (Schneppenheim and Greiner, 2006). Elevations in lipoprotein(a) (reduces fibrinolytic capacity) have been implicated as a significant risk factor for both venous and arterial thrombosis in the German

and Dutch registries; however, generalizing these findings to all populations remains unclear (Nowak-Gottl et al., 1999b, 1999c).

Lupus anticoagulant, anticardiolipin antibody, anti- β_2 -glycoprotein-I antibodies, and other maternal antiphospholipid antibodies may play a significant role in neonatal TE, especially neonatal stroke. These antibodies either lead to thromboses in the placenta or are transported across the placenta and may serve as a nidus for thrombosis formation (Chalmers, 2005; Manco-Johnson, 2008; Nelson, 2008). A recent review of 16 infants with a history of maternal antiphospholipid antibodies and perinatal thrombosis found that 13/16 had arterial thromboses, with 8/16 presenting as strokes. Therefore mothers of and/or infants with significant arterial or venous TE events should be screened for the presence of antiphospholipid antibodies (Boffa and Lachassinne, 2007).

Locations of Neonatal Thromboses, Imaging Modalities to Diagnose Them, and Management Guidelines for Specific Thromboses

Neonatal TE events may occur in a variety of locations (Table 79.6). The majority of symptomatic events are usually identified by proper imaging modalities (Table 79.6). However, difficult intravenous access, desire to limit radiation exposure, lower glomerular filtration rates, and inaccessibility to perform specific testing at the bedside limit neonatal use of many of the gold standard techniques used in adults and children (Rajagopal et al., 2016). Therefore Doppler ultrasonography is the most widely and safely used modality. The small diameter of certain vessels, low pulse pressure, and the presence of a CVC at the site of thrombus may limit interpretation of the results (Rajagopal et al., 2016).

Arterial Thromboses

Perinatal Arterial Ischemic Stroke

The majority of neonatal arterial TE events are represented by perinatal arterial ischemic stroke (PAIS). Perinatal stroke refers to an insult, ischemic or hemorrhagic, occurring from 20 weeks' gestational age to 28 days' postnatally. The subcategories of perinatal stroke and their presenting symptoms are shown in Table 79.7 (Greenway et al., 2004; Raju et al., 2007; Gacio et al., 2015). Arterial stroke in neonates is referred to as PAIS for the remainder of the chapter (cerebral sinovenous thromboses are presented later). PAIS refers to a condition with acute encephalopathy, seizures, or neurologic deficits presenting in the term or preterm infant before the 29th postnatal day with brain imaging confirming a parenchymal infarct in the appropriate arterial territory (Fig. 79.1) (Fernandez-Lopez et al., 2014; Gacio et al., 2015). PAIS is responsible for 22%–70% of congenital hemiplegic cerebral palsy in neonates (Lynch and Nelson, 2001; Lynch et al., 2001; Chalmers, 2005) as well as other neurologic comorbidities, including seizure disorders, delayed language development, and behavioral disorders (Nelson, 2008).

The incidence of PAIS ranges from 20 to 63.4 per 100,000 live births and depends on whether or not events diagnosed after the first month of life were included (Schulzke et al., 2005; Laugesaar et al., 2007). Most abnormalities occur in the left hemisphere within the distribution of the middle cerebral artery, with anterior and posterior cerebral artery lesions being less common (Chalmers, 2005; Hunt and Inder, 2006). The origin of the left carotid artery from the aorta allows a more direct vascular route to the brain as a corridor for cardiac emboli. Rarely, multifocal

TABLE 79.6**Locations of Neonatal Thromboses and the Best Imaging Modalities to Diagnose Them**

| Vessel | Type of Thromboses (Vessels Potentially Involved) | Imaging Modality |
|-----------------|--|-------------------------------------|
| Arterial | Perinatal arterial ischemic stroke (Left middle cerebral artery, anterior cerebral artery, posterior cerebral artery) | Diffusion-weighted MRI/MRA |
| | Iatrogenic (Abdominal aorta, radial artery, renal artery, mesenteric artery, popliteal artery) | Doppler ultrasound |
| | Spontaneous (Iliac artery, left pulmonary artery, aortic arch, descending aorta, renal artery) | |
| Venous | Iatrogenic/spontaneous vessel occlusion (SVC, IVC, hepatic vein, subclavian vein, abdominal veins, peripheral veins) | |
| | Renal vein | |
| | Portal vein | |
| | Cerebral sinovenous (Superior sagittal sinus, transverse sinuses of the superficial venous system, straight sinus of the deep system) | Diffusion-weighted MRI w/venography |
| | Congenital heart disease related (Right/left atria, right/left ventricle, SVC, IVC) | Echocardiography |

IVC, Inferior vena cava; MRA, magnetic resonance angiogram; MRI, magnetic resonance imaging; SVC, superior vena cava.

TABLE 79.7**Subcategories of Perinatal Stroke and Their Presenting Symptoms**

| Subcategory | Description | Symptoms |
|---|--|--|
| Neonatal arterial ischemic stroke | Occurs after birth but before 29th day of life | Seizures (focal), apnea, chewing or bicycling movements, |
| Perinatal arterial ischemic stroke | Difficult to establish whether stroke occurred before, during, or after childbirth but occurs from 20 weeks' gestational age until birth | persistent feeding difficulties |
| Presumed perinatal ischemic stroke | Subtle initial symptoms with later sequelae observed | |
| Neonatal cerebral sinovenous thrombosis | | Seizures, apnea, lethargy, irritability, poor feeding, jitteriness, thrombocytopenia, anemia, changes in muscle tone |

References (deVeber et al., 2001; Golomb et al., 2004; Chalmers, 2005; Hunt and Inder, 2006; Raju et al., 2007; Kersbergen et al., 2011; Moharir et al., 2011; van der Aa et al., 2014; Gacio et al., 2015).

cerebral infarctions can occur, and these tend to be embolic in origin (Fig. 79.2). Many potential risk factors have been implicated in the etiology of PAIS (Table 79.2).

Placental pathology is a major risk factor for PAIS. Maternal/fetal conditions that may result in decreased placental reserve, thromboinflammatory processes leading to placental blood vessel

• **Fig. 79.1** Axial diffusion-weighted magnetic resonance imaging demonstrating areas of high signal in bilateral frontal and parietal lobes, left occipital lobe, left thalamus, and left pons.

thrombosis, and sudden catastrophic events may result in emboli that break off from the placental circulation and enter the fetal circulation, passing through a patent foramen ovale with a predilection to enter the left middle cerebral artery (Elbers et al., 2011).

Prothrombotic disorders (Box 79.1) have a role in PAIS (Kenet et al., 2010). In a study of 91 full-term neonates with PAIS, prothrombotic risk factors, most commonly lipoprotein(a), were identified in 68% of these neonates compared with 25% in controls (Gunther et al., 2000). A more recent study of 24 neonates with

• **Fig. 79.2** Three-dimensional (3D) maximum intensity projection image from a 3D time-of-flight magnetic resonance angiography demonstrates occlusion of the right internal carotid artery at its origin (*arrow*). The vertebral arteries are diminutive (*arrowheads*), and the basilar artery is not visualized.

PAIS identified prothrombotic disorders (protein C deficiency most common) in 28.6% of neonates (Mercuri et al., 2001). There has also been speculation that the presence of a prothrombotic disorder in a neonate with PAIS may indicate a worse neurologic outcome (Mercuri et al., 2001).

There are no randomized clinical trials addressing the management of neonates with PAIS. Current guidelines from the American College of Chest Physicians recommend anticoagulation for neonates with PAIS if there is an ongoing cardioembolic source or if there is evidence of recurrent PAIS. Otherwise, supportive care is recommended (Monagle et al., 2012; van der Aa et al., 2014). Treatment, if necessary, ultimately depends on the acute clinical situation and the specific hemorrhagic risks for that neonate.

Magnetic resonance imaging (MRI) with diffusion-weighted imaging (DW MRI) is the most sensitive technique for the early detection of PAIS (Venkataraman et al., 2004). This technique allows for the detection of cerebral edema, which is an early sign of cerebral ischemic damage (Lovblad et al., 2001; Mader et al., 2002). Angiography allows for the detection of thromboses if there is a history of instrumentation/difficult delivery. Although cranial ultrasound (CUS) is the least-invasive method for diagnosing PAIS, it is also the least sensitive. One study found that 75% of cases of neonatal PAIS were missed when CUS was used (Estan and Hope, 1997). Therefore PAIS should never be excluded in any neonate based on negative computed tomography or CUS results.

Iatrogenic/Spontaneous Arterial Thromboses

Used for continuous monitoring of arterial blood pressure and blood gases, UACs and peripheral arterial lines (PALs) are frequently

• **Fig. 79.3** Arterial Thrombosis With Skin Necrosis.

• **Fig. 79.4** Aortic Thrombus Diagnosed by Magnetic Resonance Imaging.

used in ill neonates admitted to the NICU. Approximately 10%–64% of newborns admitted to the NICU require placement of a UAC (Saxonhouse, 2015). Femoral arterial catheters are used less frequently but are more commonly used in neonates with congenital heart disease or those requiring extensive surgery. Despite their important role, neonatologists must remember that complications from arterial catheters occur and range from line dysfunction/infection to limb/organ-threatening ischemia, as demonstrated in Figs. 79.3–79.4.

The incidence of arterial thromboses from UACs based on autopsy reports has ranged from 9% to 28% (Richardson et al., 2002), whereas the incidence of PAL-related thromboses is unknown. Potential short-term and long-term complications of UACs include mesenteric ischemia, hypertension, renal dysfunction/failure, limb loss, and congestive heart failure (Seibert et al., 1991; Greenberg et al., 1998; Nouri et al., 2007). High UAC positioning (T6–9) has been found to have fewer clinical complications (Barrington, 2000d), while low-dose continuous heparin infusion at 1 u/mL prolongs catheter patency but does not reduce the risk of thrombosis (Barrington, 2000c). Clinical signs of PAL-related

• **Fig. 79.5** Arterial Thrombosis of Digital Artery.

thrombosis include limb ischemia, pale or cold extremities distal to the cannulation site, weak or absent pulse, and decreased or immeasurable blood pressure (Fig. 79.5) (Veldman et al., 2008). Catheter material, duration of placement, and solutions infused influence the risk for both UAC-related and PAL-related thrombosis.

Suspicion or confirmation of an arterial thrombosis should warrant immediate removal of the arterial catheter. Vascular spasm may occur, and removal of the catheter may simply resolve symptoms. If symptoms of spasm persist, further actions are needed. An approach to the neonate with vascular spasm is shown in Fig. 79.6. If thrombosis is suspected, the most sensitive method to diagnose an arterial catheter-related thrombosis is contrast angiography (Greenway et al., 2004), but because of its risk in neonates, it is generally reserved for older children and adults. As a result, Doppler ultrasound is mainly employed.

Management options for neonates with a peripheral arterial catheter-related TE event are to remove the catheter with only supportive care, anticoagulation following catheter removal if there are nonlimb-threatening symptoms, or thrombolysis if there are limb-threatening symptoms (Monagle et al., 2012).

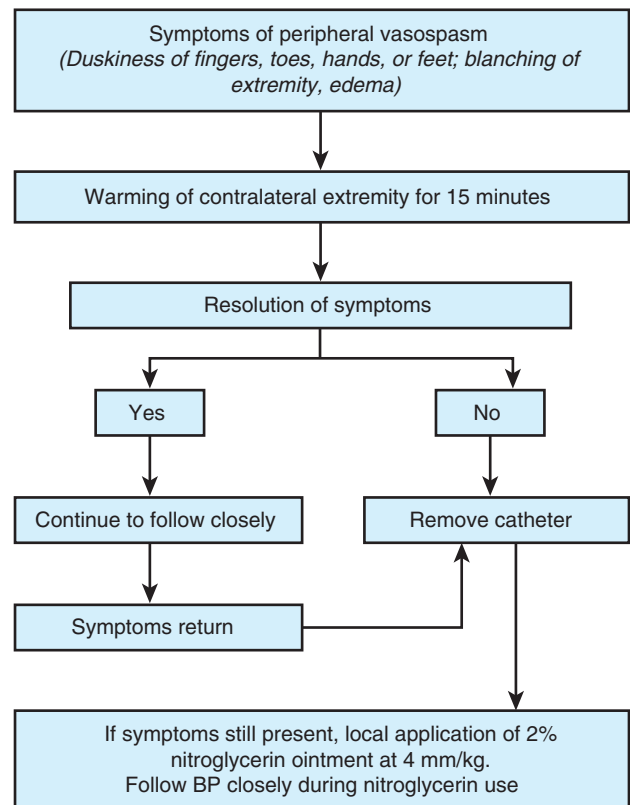

Management options for femoral arterial catheter-related thromboses are shown in Table 79.8. Dosing guidelines for thrombolysis and/or anticoagulation related to clinically significant iatrogenic or idiopathic aortic thromboses are shown in Tables 79.9–79.11.

Venous Thrombosis

The biggest risk for the development of venous thromboses in neonates admitted to the NICU is the presence of a CVC. Additional risk factors (Table 79.2) combined with the presence of a CVC further increase this risk.

Catheter-Related Thrombosis (Umbilical Venous Catheters and Peripherally Inserted Central Venous Catheters)

Premature and sick newborns greatly benefit from CVCs. Infusion of life-saving medications and enhanced nutrition lead to better outcomes, but risks for thrombosis, infection, malfunction, and death exist. Neonatologists and others caring for neonates admitted to the NICU must weigh the benefit versus the risk every day that

• **Fig. 79.6** Management of Peripheral Vasospasm. Current recommendations for the evaluation and management for neonates with peripheral vasospasm caused by complications from peripheral arterial lines and umbilical arterial catheters. Nitroglycerin dosing is provided. BP, Blood pressure.

a CVC remains in place, and the catheter should be removed as soon as necessary. Damage to blood vessel walls during insertion, disrupted blood flow, infusion of substances that damage endothelium, and thrombogenic catheter materials are the main reasons that thromboses develop (Bhat and Monagle, 2012; Sellitto and Messina, 2012).

Neonates, especially very low birth weight infants (<1500 g), routinely have umbilical venous catheters (UVCs) placed during the first few days of life as peripheral access may be difficult to secure. Despite their clinical importance, UVCs represent the most common cause for thrombosis in premature infants (Rajagopal et al., 2016). The exact incidence of UVC-related thrombosis varies, but recent reports have ranged from 21% to 71% (dependent on how aggressive centers screened for asymptomatic thrombosis) and include portal vein, renal vein, and inferior vena cava (IVC) thrombosis (Bhat and Monagle, 2012). Autopsy studies have estimated that 20%–65% of infants who die with a UVC in situ have microscopic evidence of TE (Schmidt and Zipursky, 1984; Kulkarni and Lusher, 2001; Tanke et al., 1994). Intracardiac thrombosis from UVC placement ranges from 1.8% to 5.3% (Bhat and Monagle, 2012).

Clinical signs and symptoms suggestive of a UVC-related thrombosis include persistent infection, persistent thrombocytopenia, line dysfunction, and bilateral lower limb edema (Fig. 79.7) (Monagle et al., 2012). The Centers for Disease Control and Prevention recommend that use of UVCs be limited to 14 days (O'Grady et al., 2002). A randomized trial comparing long-term UVC use (up to 28 days) with short-term (7 to 10 days) use

TABLE 79.8 Management of Femoral Artery Thrombosis

| Treatment | Severity of Thrombosis | Description |
|---|---|---|
| IV UFH (see Table 79.9) | Acute femoral artery thrombosis but nonlimb threatening | Treatment should continue until clot resolution but should not be for more than 5–7 days. May convert to LMWH (Table 79.10) after 48–72 hours of treatment and continue until clot resolution |
| IV UFH followed by rt-TPA if clot does not improve or symptoms worsen (see Tables 79.9 and 79.11) | Limb-threatening or organ-threatening femoral artery thrombosis | Begin IV UFH (see Table 79.9), but if symptoms do not improve within 24–48 hours, may begin rt-TPA with UFH (see Table 79.11). If rt-TPA contraindicated, may need surgery |

LMWH, Low-molecular-weight heparin; UFH, unfractionated heparin; rt-TPA, recombinant tissue type plasminogen activator.

Data from references (Streif et al., 2003; Michaels et al., 2004; Obaid et al., 2004; Manco-Johnson, 2006; Malowany et al., 2007, 2008; Monagle et al., 2012).

TABLE 79.11**Clinical Indications and Recommended Dosing Guidelines for rt-TPA Therapy in Neonates**

| Clinical Situation | Gestational Age | Recommended Dosing | Appropriate Monitoring |
|--------------------------------|-----------------|---|--|
| Limb/life-threatening thrombus | <28 weeks | 0.03–0.06 mg/kg per h Infuse UFH at 10 U/kg per h | Dose escalation up to 0.24 mg/kg per h can be considered but has to be done slowly with continuing monitoring of the patient (see Table 79.17). Supplementation with plasminogen (FFP at 10 mL/kg) before commencing therapy is recommended to ensure adequate thrombolysis (Monagle et al., 2012). |
| | >28 weeks | May use same as for <28 weeks or may use 0.1–0.5 mg/kg per h for 6–12 hours with repeat daily dosing for up to 3 days Infuse UFH at 10 U/kg per h during rt-TPA infusion | |

FFP, Fresh frozen plasma; rt-TPA, recombinant tissue type plasminogen activator; UFH, unfractionated heparin.

–If no clot dissolution occurs 12–24 hours after starting infusion and/or D-dimers are not increasing, may give an additional 10 mL of FFP to provide additional plasminogen to increase efficacy of rt-TPA.

–Discontinue infusion when clot dissolved (maximum of 96 hours).

–Maintain fibrinogen levels greater than 100 mg/dL (provide cryoprecipitate if less than 100 mg/dL) and platelet counts greater than $50 \times 10^9/\mu\text{L}$.

followed by peripheral central venous line placement demonstrated that 4% of neonates in the short-term group compared with 7% of neonates in the long-term group developed significant thromboses (detected by echocardiogram). However, all of the thrombi were at the site of the UVC tip, and none of the neonates required treatment (Butler-O'Hara et al., 2006).

To enhance nutrition and to administer long-term parenteral medications, peripherally inserted central venous catheters (PICVs) or surgically placed CVCs are routinely placed in preterm and ill neonates and tend to remain in place for weeks until treatment is finished or an infant reaches full enteral feedings. Clinical signs of PICV and surgically placed CVC-related thrombosis include unilateral limb swelling/pain/dyscoloration, superior vena cava syndrome, chylothorax, chylopericardium, intracardiac thrombosis, unresolving sepsis, thrombocytopenia, and cardiac failure (Andrew et al., 2001; Saxonhouse and Burchfield, 2009; Rajagopal et al., 2016).

The gold standard for diagnosing venous TE is MR venogram; however, this modality is difficult to perform in neonates (Greenway et al., 2004). Ultrasound is therefore the most widely and safely used modality. False-negative results often occur when evaluating

for thromboses in the upper central venous system because of obstruction of the distal subclavian veins by the clavicles. In addition, compression of veins in a central location by the probe is not feasible because of the neonate's rib cage (Albisetti et al., 2005).

Long-term complications of venous TE include chronic venous obstruction with prominent cutaneous collateral circulation, chylothorax, portal hypertension, and embolism. More children are now presenting with postthrombotic syndrome who had a previous history of a neonatal venous TE (Barnes et al., 2002).

There are two options regarding the management for CVC-related thromboses. The first is to initiate anticoagulation followed by the removal of the catheter after 3 to 5 days of anticoagulation. Anticoagulation (dosing provided in Tables 79.9–79.10) should continue until there is resolution of the thrombus, and treatment may last from 2 weeks to 3 months, depending on the size, location, and symptoms of the thrombus (Monagle et al., 2012). The second option is to provide supportive care only with immediate removal of the catheter. Radiologic monitoring should continue for clot extension. If clot extension does occur, then anticoagulation should begin (Monagle et al., 2012).

Intracardiac Thromboses and Thromboses in Infants With Complex Congenital Heart Disease

The placement of a CVC into the right atrium may lead to damage of the endocardium, inducing either pericardial tamponade and/or the development of intracardiac thrombi. The development of intracardiac vegetations secondary to CVC infections may expose an infant to prolonged infection and dissemination of septic emboli. Thrombus formation in the right atrium and superior vena cava has been associated with a high endocarditis risk, sepsis persistence, pulmonary artery obstruction, ventricular dysfunction, acute hemodynamic compromise, and death (Schmidt and Andrew, 1995; Torres-Valdivieso et al., 2003; Hermansen and Hermansen, 2005; Ulloa-Ricard et al., 2015).

Thrombosis is a common complication reported in neonates undergoing repair for complex congenital heart disease (Chollette et al., 2007). Less is known about neonates undergoing initial palliative procedures for single ventricle physiology. A retrospective review of neonates who underwent palliative repair found that in patients who died and had autopsies available, 33% of deaths were attributable to thrombosis (Fenton et al., 2003). A more recent

review of 22 neonates who underwent palliative repair between 1 and 11 days of life found evidence of thrombi in 5 infants (23%) (Chollette et al., 2007).

A recent case-control study performed at a high-level referral NICU demonstrated an incidence of intracardiac thrombosis of 22.5 cases per 1000 admissions (Ulloa-Ricardez et al., 2015). Many of these infants were critically ill and had complex congenital heart disease. Major risk factors from this study included prematurity, maternal history of gestational diabetes/diabetes mellitus, surgical cut-down technique to place a CVC, and *Staphylococcus epidermidis* infection. In addition, almost one-quarter of these infants died despite receiving treatment for the thrombosis (Ulloa-Ricardez et al., 2015).

Echocardiography is the preferred modality for diagnosing either right atrial thrombus formation, intracardiac vegetations, or thrombus formation in infants with single ventricle physiology. Signs suggestive of an atrial thrombus include new-onset murmur, persistent sepsis, persistent thrombocytopenia, and cardiac failure. The surgical approach to remove the thrombus in neonates is not feasible, especially the premature infant. There have been case reports using recombinant tissue type plasminogen activator (rt-TPA) for thrombolysis of catheter-related atrial thrombus in the neonate (Rimensberger et al., 2001; Torres-Valdivieso et al., 2003; Wang et al., 2003; Tardin et al., 2007). rt-TPA has also been used successfully in the management of premature infants with infective endocarditis (Marks et al., 2002).¹⁶

Renal Vein Thrombosis

The majority of cases of neonatal renal vein thrombosis (RVT) present in preterm infants usually during the first month of life (Bokenkamp et al., 2000; Lau et al., 2007). RVT is the most common spontaneous venous TE in neonates, with an incidence of about 0.5 per 1000 NICU admissions (Schmidt and Andrew, 1995). A review of 271 neonatal cases demonstrated that 70% of cases were unilateral, with 64% of these involving the left kidney, and males were more frequently affected (Messinger et al., 2006; Lau et al., 2007). These findings were supported by a more recent review of 10 cases (Bidadi et al., 2016). The cardinal signs suggestive of RVT are macroscopic hematuria, a palpable abdominal mass, and thrombocytopenia, with the most recent study demonstrating this triad in 50% of patients (Bidadi et al., 2016). Other symptoms include oliguria, proteinuria, acute renal failure, and hypertension. Risk factors (shown in Table 79.2) are frequently found in RVT cases. The most recent study demonstrated risk factors in 90% of infants with RVT, with 50% having at least three risk factors: prematurity and perinatal asphyxia are the most common (Bidadi et al., 2016). Prothrombotic risk factors have been found in varying numbers of neonatal cases of RVT, with studies finding at least one prothrombotic risk factor in 17%–67% of cases (Kosch et al., 2004; Marks et al., 2005; Lau et al., 2007; Bidadi et al., 2016). Because of the potential association of prothrombotic disorders and RVT, an evaluation for an inherited thrombophilia is warranted.

The diagnosis of RVT is usually made via Doppler ultrasound. Radiographic criteria for RVT include presence of echogenic clot, venous distention secondary to the presence of a thrombus, or absence of flow (Bidadi et al., 2016).

The treatment for RVT is controversial, as there are no large randomized clinical trials addressing the issue. However, complications of RVT are serious and include adrenal hemorrhage, extension of the clot into the IVC, renal failure, hypertension, and death (Lau et al., 2007). One study demonstrated the development of hypertension in 19% and 22% of neonates with unilateral and

**TABLE

bilateral RVT, respectively (Lau et al., 2007). The most recent treatment recommendations based on observational and case series and expert opinion are shown in Table 79.12 (Monagle et al., 2012). The most recent analysis demonstrated that anticoagulation and fibrinolysis appeared to prevent worsening of renal failure in neonates with bilateral RVT. However, renal atrophy did not seem to change whether supportive care or anticoagulation/fibrinolysis was used, suggesting that many of these events may be in utero and chronic in nature (Bidadi et al., 2016).

Portal Vein Thrombosis

The two main risk factors for the development of portal vein thrombosis (PVT) in neonates are sepsis/omphalitis and UVC use (Williams and Chan, 2011). Most cases tend to be clinically silent, making the diagnosis difficult. Incidences vary (because of aggressiveness of imaging in asymptomatic patients) between 1% and 43% (Kim et al., 2001; Williams and Chan, 2011). Ultrasound is the preferred modality for diagnosis, and findings of cavernous transformation of the portal vein with subsequent splenomegaly and reversal of portal flow are used to document its severity (Williams and Chan, 2011). Spontaneous resolution of asymptomatic PVT is relatively common, but the detection of PVT, even in asymptomatic patients, warrants close observation in order to follow for signs of portal hypertension. This complication may manifest itself up to 10 years after the neonatal period (Williams and Chan, 2011). Management options, based on limited clinical data, are provided in Table 79.13 (Williams and Chan, 2011).

Cerebral Sinovenous Thrombosis

Cerebral sinovenous thrombosis (CSVT) represents a subcategory of perinatal stroke (O'Brien, 2015). Symptoms are similar to PAIS and include seizures, apnea, lethargy, irritability, poor feeding, jitteriness, or changes in muscle tone (deVeber et al., 2001; Wasay et al., 2008). These may be accompanied by anemia and/or thrombocytopenia. A recent review demonstrated that 90% of children who presented with CSVT had predisposing risk factors

(Table 79.2 and Box 79.1), with 16% of these patients having multiple risk factors (Wasay et al., 2008; Kenet et al., 2010). The most common risk factors were infections (40%), perinatal complications (25%), and prothrombotic traits (13%) (Wasay et al., 2008). The presentation of any of the above symptoms in a neonate with any of these risk factors should alert the clinician to screen for CSVT.

The superficial and lateral sinuses are the most frequently involved vessels (Chalmers, 2005), and up to 30% of cases have reported

venous infarction with subsequent hemorrhage (Wu et al., 2003). Impaired or absent venous drainage in one of the cerebral sinuses leads to increased venous pressure, vasogenic edema, and secondary infarction. Intraventricular hemorrhages (especially in term neonates) and hemorrhages within the caudate nucleus and thalamus are associated with thrombosis of the deep cerebral venous sinuses. Therefore the presence of an intraventricular hemorrhage or thalamic hemorrhage in a term or late preterm infant warrants exclusion of CSVT (Wu et al., 2003). Diagnosis of CSVT is best made through diffusion MRI with venography (Manco-Johnson, 2006; Monagle et al., 2012; O'Brien, 2015; Rajagopal et al., 2016).

Neonatal CSVT mortality rates have ranged from 2% to 24% (Moharir et al., 2011). Long-term follow-up of neonates diagnosed with CSVT has demonstrated neurologic deficits, consisting of cerebral palsy, epilepsy, and cognitive impairments in 10%–80% of infants (Berfelo et al., 2010; Kersbergen et al., 2011; Moharir et al., 2011).

The role of anticoagulation for CSVT is controversial, and recommendations for management are not based on clinical trials (Jordan et al., 2010; Moharir et al., 2010; Monagle et al., 2012). Current treatment recommendations are shown in Fig. 79.8. Surgery is reserved for those with hydrocephalus or large intracerebral hematomas with mass effect.

Prothrombotic Laboratory Evaluation for Clinically Symptomatic Neonatal Thromboses

The question remains whether every neonate diagnosed with a clinically significant thrombosis should have a full evaluation for a prothrombotic disorder (Box 79.1). Does the presence of acquired risk factors (Table 79.2) provide enough risk to avoid searching for a possible prothrombotic trait? Does a critically ill neonate with a CVC-related venous thrombosis warrant a full prothrombotic evaluation (Greenway et al., 2004; Gursel et al., 2007; Turebylu et al., 2007)? Definitive answers to these questions remain unknown, but based on the current evidence from data registries, case series, case reports, and expert opinion, a stepwise investigation for a prothrombotic disorder should be performed based on the type and severity of the thrombosis and the number of acquired risk

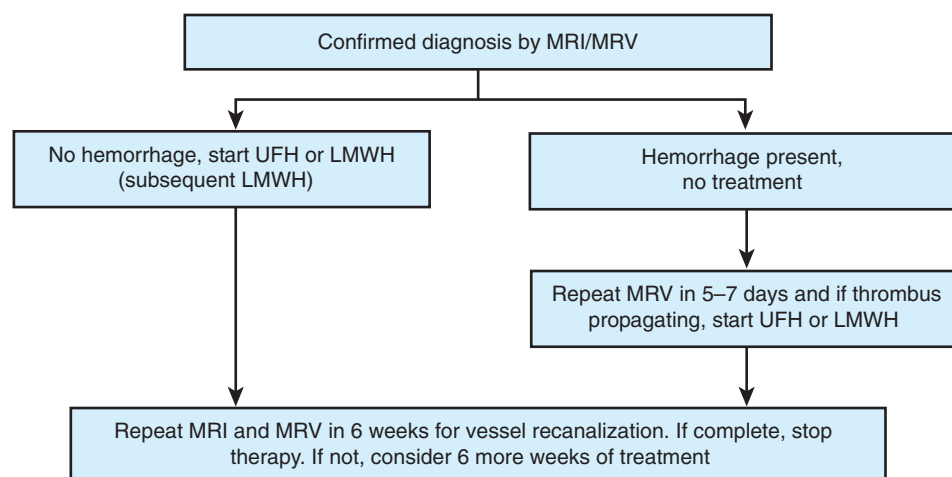

TABLE 79.13 Management Options for Neonates With Portal Venous Thrombosis

| Treatment Plan | Description of PVT | Recommended Ultrasound (US) Follow-Up |
|------------------------------|---|---|
| Observation | No extension observed and infant clinically stable | 7–10 days |
| Anticoagulation ^a | Extension into the IVC, RA, and/or RV but no end-organ compromise | 10 days If thrombus resolved, may stop therapy. If still present, treat for 6 weeks to 3 months, depending on US follow-up |
| Thrombolysis ^a | End-organ compromise with extension of the thrombosis into the IVC, RA, and/or RV | Daily May stop thrombolysis when symptoms improve but would transition to anticoagulation |

^aFor dosing options, please see Tables 79.9–79.11.

• BOX 79.2 Key Points Regarding the Laboratory Evaluation for a Prothrombotic Disorder

- Because of many of the pro/anticoagulation protein levels being lower than adult values, the diagnosis of a coagulation disorder may be difficult in the immediate neonatal period.
- Certain protein-based assays may aid in treatment during the neonatal period (antithrombin III and plasminogen assays) and may be performed during the neonatal period.
- DNA-based assays are accurate and may be obtained at any time.
- Lipoprotein(a) concentrations increase during the first year of life and should be repeated at 8–12 months of life if values obtained at 3–6 months are low, especially in Caucasian individuals.
- The different evaluations listed below are based on the presence of acquired risk factors, type of thrombosis, severity of thrombosis, and treatment regimen.
- Baseline complete blood count, prothrombin time, activated partial thromboplastin time, and fibrinogen levels should be obtained shortly after the acute event.
- Antiphospholipid antibody panels should be obtained from the mother and may warrant coordination with obstetrics.
- Placental pathology, especially in cases of perinatal arterial ischemic stroke, should be requested.

Adapted from Saxonhouse MA. Thrombosis in the neonatal intensive care unit. *Clin Perinatol.* 2015;42:651–673.

factors. Timing of the evaluation is important, with certain aspects being performed immediately following an acute event and other aspects being performed at 3 to 6 months of life. Key points and a comprehensive laboratory evaluation based on acquired risk factors are listed in Table 79.14, Table 79.15, and Box 79.2. The clinician

may choose to add or delete tests based on the presentation, family history, or timeframe of the event.

The large amount of blood that traditionally has been required to perform this evaluation has always been a criticism: therefore the evaluation should take place at an experienced tertiary care center that has the ability to perform these tests or has a reliable referral center. This approach dramatically reduces the amount of blood required, as it is specifically designed for neonates. Although anticoagulation treatment is not usually started based on a prothrombotic evaluation, the identification of a disorder may help prevent future thromboses during childhood and adolescence. Anticoagulation before certain medical or surgical procedures may help to avoid the development of a significant thromboses and truly be beneficial to the future health of the patient.

Management of Thrombosis

The use of anticoagulant/fibrinolytic therapy in the NICU carries the significant risk for bleeding, especially ICH. Many clinicians are hesitant to start therapy, even when the benefits outweigh the risks. Specific neonatal formulations for antithrombotic agents are limited, making accurate and reproducible weight-adjusted dosing difficult (Manco-Johnson, 2006; Monagle et al., 2012).

The majority of recommendations and dosing regimens for anticoagulant/fibrinolytic therapy in neonates are based on case series, cohort studies, and expert opinion. Goals for fibrinolysis are restoration of blood flow preserving organ function and

preventing catastrophic long-term complications, including death. Goals for anticoagulation are prevention of recurrent thromboses and serious sequelae from embolism (Bhatt et al., 2015). Before initiating any therapy, consideration for serious complications must be noted, and the treatment's benefits must outweigh its risks, especially in the premature infant. Family discussions highlighting the risks and goals for treatment must be documented before initiating any therapy. Treatment should occur at a tertiary care center that has proper laboratory, blood bank, pharmacy, pediatric radiological subspecialty, pediatric hematological subspecialty, and pediatric surgical support (Monagle et al., 2012). The clinician should refer to the most recent American College of Chest Physicians (CHEST) guidelines (Monagle et al., 2012) or may use the service 1-800-NO CLOTS to receive up-to-date management guidance. Before initiating any treatment, absolute and relative contraindications to antithrombotic therapy should be reviewed (Table 79.16).

Unfractionated Heparin

The use of unfractionated heparin (UFH) should be limited to clinically symptomatic thromboses that are not life or limb threatening. Heparin inhibits numerous coagulation factors and platelet function, produces a release of TFPI from endothelial cells, and enhances fibrinolysis (Schulman, 2013). UFH achieves its main anticoagulant effect by binding to antithrombin, catalyzing its ability to inactivate thrombin and factor Xa (Pratt and Church, 1991). The dosing of UFH in neonates is affected by many factors, including lower AT levels, increased binding of UFH to plasma proteins, and faster clearance in neonates compared with adults (McDonald et al., 1981; Andrew et al., 1988a, 1992; Monagle et al., 2006). These differences explain why neonates tend to require a higher infusion rate to reach therapeutic levels than do adults (Newall et al., 2009a; Ignjatovic et al., 2010). Current dosing guidelines for neonates with and without loading doses are provided in Table 79.9. Dosing regimens for UFH tend to vary, based on the source referenced and age of the infant. Larger prospective studies are needed to better define UFH dosing in neonates and whether or not a loading dose is necessary.

The most recent review of UFH dosing in neonates *does not recommend* a loading dose (Bhatt et al., 2015). Increased bleeding risk with use of a loading dose and low risk for recurrent thrombosis with no evidence suggesting that recurrent thromboses are due to

subtherapeutic antifactor Xa levels during the first 24 hours of anticoagulation are why loading doses were not recommended (Bhatt et al., 2015). Loading doses should be reserved for neonates with significant risk or evidence for thrombus progression.

Proper laboratory monitoring of UFH therapy is crucial to reducing bleeding complications (Table 79.9). The two currently used tests are the anti-Xa assay and the APTT. The anti-Xa assay measures UFH's ability to catalyze AT's inhibition of factor Xa (Bhatt et al., 2015). An anti-Xa value of 0.35–0.7 U/mL is considered therapeutic (Basu et al., 1972; Levine et al., 1994). There are two types of anti-Xa assays: one with exogenous AT added and another without exogenous AT (Newall et al., 2009b). Clinicians should be aware which assay their laboratory is using before monitoring is performed (Bhatt et al., 2015). The APTT allows for quick and easy measurement of the effect of UFH (Bhatt et al., 2015), using an APTT value of 60–85 seconds serves as an indicator of therapeutic anticoagulation in neonates (Monagle et al., 2012). Neonatal limitations of the APTT include a higher baseline value and a smaller prolongation with UFH, thus underestimating or overestimating in vivo heparin activity. Based on these limitations, one possible approach to measuring therapeutic anticoagulation using UFH in neonates is to use a combination of the anti-Xa assay and APTT (dependent on whether centers can perform both tests) (Bhatt et al., 2015). After initiating UFH therapy, an anti-Xa level and an APTT should be measured 6 hours later (Monagle et al., 2012). If both are therapeutic, daily CBC and anti-Xa and APTT levels should be monitored. This specific regimen is difficult to perform in neonates (especially premature) as significant phlebotomy losses occur, so a more reasonable approach is to perform both tests 6 hours after initiating therapy and then monitoring anti-Xa levels with periodic APTT values (Table 79.9). If the APTT is elevated and out of proportion to the anti-Xa level, a possible coagulopathy may exist (Bhatt et al., 2015). If the APTT is low compared with the anti-Xa level, an elevated FVIII level may exist (Kurekci et al., 2003; Goldenberg et al., 2004). Finally, a persistently low anti-Xa level suggests antithrombin deficiency, and a level should be obtained (Bhatt et al., 2015). Supplementation may need to occur, but one must remember that dosing is based on lower antithrombin levels (Manco-Johnson, 2006, 2008; Monagle et al., 2012). UFH therapy should be limited for short-term use, and attempts to convert to lower molecular weight heparin (LMWH) should be done if longer therapy is required. Therapy is usually limited to 2 to 14 days, but data to support this recommendation are lacking (Monagle et al., 2012).

Bleeding is the most significant complication of UFH therapy in neonates. The largest study evaluating 38 neonates being treated for CSVT had a bleeding risk of 8% (Moharir et al., 2010). More recently, a risk of 11% was observed with UFH therapy in infants less than 6 months old (Schechter et al., 2012). Because of the risks for intraventricular hemorrhage in preterm and term infants, CUS should be performed before and during treatment. Treatment of hemorrhage usually only requires cessation of the infusion because of UFH's short half-life. If the infusion is stopped but bleeding continues, then protamine should be given at a dose of 1 mg per 100 units of heparin received if the last heparin dose was administered less than 30 minutes previously and 0.25 mg protamine per 100 units of heparin if the last heparin dose was administered as long as 120 minutes before (Saxonhouse and Manco-Johnson, 2009). Other complications such as heparin-induced thrombocytopenia, although common in adults and children, rarely occurs in neonates, and only a few cases have been

reported (Spadone et al., 1992; Martchenko and Boshkov, 2005). The most recent systematic review in neonates demonstrated an incidence of 0% among 335 neonates treated with UFH (Avila et al., 2013). A drop in the platelet count by 50% or persistent platelet counts of less than 70–100,000/mm³ occurring 5 to 10 days after the first exposure to heparin should alert the clinician for this possible diagnosis. Lepirudin can be considered in neonates with heparin-induced thrombocytopenia, but its use has not been adequately studied in neonates (Thornburg and Pipe, 2006). Prolonged therapy with UFH (>14 days) should be avoided to prevent potential loss of calcium from bones (Bhatt et al., 2015).

Low-Molecular-Weight Heparin

Low-molecular-weight heparin (LMWH), specifically enoxaparin, has become the neonatal anticoagulant of choice because of a reduced risk of hemorrhage, subcutaneous (SQ) dosing, and reduced monitoring requirements (Streif et al., 2003; Michaels et al., 2004; Thornburg and Pipe, 2006). LMWH specifically acts against factor Xa, and its administration can be achieved either through SQ injection or the use of an indwelling SQ catheter (Insuflo; Unomedical, Birkerød, Denmark) (Manco-Johnson, 2006; Streif et al., 2003). The use of the SQ catheter reduces the number of needle sticks from 14 per week to 1 per week. However, case reports and reviews of SQ catheter usage in neonates have reported that greater than 50% of neonates experience minor adverse events, including induration, leakage, and bruising (Malowany et al., 2007). Other case reports have reported major adverse events caused by SQ catheters in three infants and one case of an infected hematoma (Streif et al., 2003; Malowany et al., 2007, 2008; van Elteren et al., 2011a, 2011b).

Recommended dosing and monitoring for infants less than 2 months of age are provided in Table 79.10. Antifactor Xa levels should be followed 4 hours after the second dose, with a goal level of 0.5–1.0 U/mL (Malowany et al., 2008). Once therapeutic, levels should be followed 1 to 2 times per week (obtained 4 hours after a specified dose). Guidelines for adjusting LMWH therapy are presented elsewhere (Monagle et al., 2012).

Maintaining therapeutic levels in neonates may be a challenge. Lack of pediatric formulations and rapid growth rates in premature infants are the main reasons (Manco-Johnson, 2006; McNinch et al., 2007). A recent review evaluating enoxaparin use in 240 neonates found that the mean maintenance dose of enoxaparin ranged from 1.48 to 2.27 mg/kg every 12 hours for all infants but was higher for preterm neonates at 1.9 to 2.27 mg/kg every 12 h (Malowany et al., 2007, 2008). These findings have influenced current recommended dosing (Table 79.10) (Malowany et al., 2008).

LMWH therapy has been effective in the NICU with centers reporting either partial or complete resolution of TE events in 59%–100% of neonates treated (Malowany et al., 2007, 2008).

Recombinant Tissue Type Plasminogen Activator

Fibrinolytic agents, specifically recombinant tissue type plasminogen activator (rt-TPA), convert plasminogen to plasmin, which cleaves fibrinogen to fibrin and fibrin degradation products (see Video 79.2). rt-TPA use in neonates should *only* be considered for limb-threatening or organ-threatening thromboses and acute atrial thrombi (Wang et al., 2003; Manco-Johnson, 2008; Monagle et al., 2012). Treatment in neonates is affected by low baseline plasminogen levels.

The safety and efficacy of rt-TPA treatment in neonates have been reported in case series and cohort studies demonstrating complete or partial clot lysis in 84%–94% of cases (Hartmann et al., 2001). Five of these cases used low-dose systemic rt-TPA treatment, demonstrating effectiveness in all neonates treated, with one preterm infant requiring discontinuation of therapy because of the development of a subdural hematoma (Wang et al., 2003). Based on limited data, recommended dosing is provided in Table 79.11, with very careful laboratory and radiologic monitoring required, and these recommendations are provided in Table 79.17. rt-TPA treatment does not inhibit clot propagation or directly affect hypercoagulability; therefore simultaneous infusion of UFH at 5–10 U/kg per hour is recommended (Wang et al., 2003; Manco-Johnson, 2006). Once the clot is adequately lysed, rt-TPA

TABLE 79.17 Monitoring Recommendations for Thrombolytic Therapy in Neonates

| Testing | When Performed | Levels Desired (if Applicable)* |
|-----------------------------------|---|---|
| Imaging of thrombosis | Before initiation of treatment Every 12–24 hours during treatment | |
| Fibrinogen level | Before initiation of treatment 4–6 hours after starting treatment Every 12–24 hours | Minimum of 100 mg/dL ¹⁰ Supplement with cryoprecipitate |
| Platelet count | Before initiation of treatment 4–6 hours after starting treatment Every 12–24 hours | Minimum of 50–100 × 10 ⁴ /μL ¹⁰ , dependent upon bleeding risk |
| Cranial imaging | Before initiation of treatment Daily during treatment | |
| Coagulation testing | Before initiation of treatment 4–6 hours after starting treatment Every 12–24 hours | |
| Plasminogen | Before initiation of treatment 4–6 hours after starting treatment Every 12–24 hours | Adequate to achieve thrombolysis Supplementation with plasminogen (FFP) before commencing therapy is recommended to ensure adequate thrombolysis ^{11,108} |
| Line associated or mucosal oozing | At all clinical assessments | Topical thrombin prn |

FFP, Fresh frozen plasma.

therapy should be discontinued, with anticoagulants, preferably LMWH, started.

Surgery

The use of microsurgical techniques and combined microsurgical and thrombolytic regimens has the potential to rapidly restore blood flow, avoiding tissue loss, without major bleeding complications, especially in patients with peripheral arterial occlusion (Coombs et al., 2006). One center's experience of 11 patients with arterial vascular access–associated thrombosis, secondary to PAL complications, described 5 patients that required arteriotomy, embolectomy, and subsequent microvascular reconstruction (Coombs et al., 2006). When faced with a significant arterial thrombosis, especially one from a PAL, surgery may be entertained but should only take place at an experienced institution.

New Anticoagulants

Of the new anticoagulant agents in adults, there is little experience in children, especially neonates. Recombinant hirudin (lepirudin) is a direct thrombin inhibitor and may be used for neonatal cases of heparin-induced thrombocytopenia (Thornburg and Pipe, 2006). The direct oral thrombin inhibitor (melagatran) has potential in the NICU but remains to be tested. Other oral antifactor Xa agents are currently being tested in the NICU and may have a major role in long-term neonatal anticoagulation. New catheter materials that are in the clinical and preclinical stage of development, such as those coated with antithrombin–heparin covalent complex, may prove to be useful in the future (Greenway et al., 2004).

Conclusion

Hemorrhagic and TE emergencies may affect neonates admitted to the NICU. Neonatologists and others caring for newborns should routinely refer to updated guidelines on what are the best treatments. The lack of randomized clinical trials for the management of TE emergencies forces neonatologists to base their medical decisions from registry and expert guidelines. The ultimate goal is to treat effectively without causing additional harm. This may be difficult when treatments, for both hemorrhage and TE, have significant risks. As our knowledge improves of the premature infant, so will our understanding of the neonatal hemostatic system. The importance of randomized clinical trials and improved center data registries

investigating treatment options for neonatal hemorrhage and TE thrombosis cannot be ignored. As we begin to answer the mysteries of the neonatal hemostatic system, it is only hoped that we uncover what are the best preventive and safest treatment strategies.

Neonatal Platelet Disorders

EMÖKE DESCHMANN AND MARTHA C. SOLA-VISNER

KEY POINTS

- Mild to moderate, early-onset thrombocytopenia in well-appearing small for gestational age neonates is usually caused by placental insufficiency and resolves spontaneously within 10–14 days.
- Neonates with platelet counts less than $50 \times 10^9/L$ in the first day of life should be screened for neonatal alloimmune thrombocytopenia and should be treated with random donor platelets (\pm intravenous immunoglobulin) as the first line of therapy, unless human platelet antigen (HPA)-1b1b and HPA-5a5a platelets are immediately available for use.
- The only published randomized controlled trial of neonatal platelet transfusions was limited to infants less than 1500 g during the first week of life and showed no differences in the frequency or severity of intraventricular hemorrhages between neonates transfused for platelet counts less than $60 \times 10^9/L$ versus less than $150 \times 10^9/L$.
- The risk of bleeding in thrombocytopenic neonates is multifactorial, but gestational age less than 28 weeks, postnatal age less than 10 days, and diagnosis of necrotizing enterocolitis are stronger predictors of bleeding than the platelet count.
- The most severe congenital platelet function defects, which can present with bleeding in neonatal life, are Bernard–Soulier syndrome and Glanzmann thrombasthenia.

Fetal and Neonatal Platelet Production

A mounting body of evidence arising over the last decade has clearly demonstrated that there are substantial morphologic and biologic differences between fetal/neonatal and adult megakaryocytes and platelets. Developmental stage-specific differences are ontogenetically important, because they allow the fetus to maintain stable platelet counts while the blood volume is rapidly expanding, in a time period characterized by exceptionally rapid growth. The complex process of platelet production can be represented as consisting of four main steps: (1) the production of thrombopoietic factors (mainly thrombopoietin [TPO]), (2) the proliferation of megakaryocyte progenitors, (3) the differentiation and maturation of megakaryocytes through a unique process of endomitosis, and finally, (4) the production and release of platelets into the circulation.

Studies culturing megakaryocyte progenitors derived from term and preterm umbilical cord blood, fetal blood (18–22 weeks' gestation), or fetal bone marrow have documented that fetal/neonatal megakaryocyte progenitors proliferate at a significantly higher rate compared with their adult counterparts. Additionally, fetal and

neonatal megakaryocytes are substantially smaller and have lower ploidy levels than adult megakaryocytes. Contrary to adult megakaryocytes, however, which mature as their ploidy level increases, neonatal megakaryocytes are fully mature and capable of platelet production despite their small size and low ploidy. This dissociation between proliferation, polyploidization, and cytoplasmic maturation is a hallmark feature of neonatal megakaryopoiesis. The net result of this process is the production of large numbers of low-ploidy but highly mature megakaryocytes, with which fetuses and neonates populate their rapidly expanding bone marrow space and blood volume, while maintaining normal platelet counts. As developmental processes are easily disturbed, however, sick neonates, and particularly very low birth weight infants (VLBW) (birth weight <1500 g), are at high risk of thrombocytopenia.

Platelet Counts During Development and Reference Ranges

Recently, Wiedmeier and collaborators published the largest study on neonatal platelet counts conducted to date, which included approximately 47,000 infants delivered between 22 and 42 weeks' gestation (Wiedmeier et al., 2009). This study showed that platelet counts at birth increased with advancing gestational age (Fig. 80.1), by approximately $2 \times 10^9/L$ for each week of gestation. Importantly, while the mean platelet count was greater than $200 \times 10^9/L$ even in the most preterm infants, the fifth percentile was $104 \times 10^9/L$ for those less than 32 weeks' gestation and $123 \times 10^9/L$ for late-preterm and term neonates (see Fig. 80.1) (Wiedmeier et al., 2009). These findings suggested that different definitions of thrombocytopenia and thrombocytosis should be applied to preterm infants. In that regard, however, it is important to emphasize that the reference ranges in that study were generated by eliminating the top 5% and the bottom 5% of all available values, rather than excluding values based on diagnoses. Thus these should be considered “epidemiologic reference ranges” rather than “normal ranges.” Nevertheless, these data suggest that platelet counts between 100 and $150 \times 10^9/L$ might be more frequent among otherwise healthy extremely preterm infants than among full-term neonates or older children/adults.

Platelet Function and Primary Hemostasis

Multiple studies evaluating platelet adhesion, aggregation, and activation have shown that neonatal platelets are hyporesponsive in vitro to most agonists, compared with adult platelets (Israels et al., 1997; Rajasekhar et al., 1997), and this hyporeactivity is

• **Fig. 80.1** First recorded platelet counts, obtained in the first 3 days after birth, in neonates born at 22 to 42 weeks' gestation. Mean values are indicated by the red line, and the 5th and 95th percentiles are shown in the blue and green lines, respectively. (Adapted from Wiedmeier SE, Henry E, Sola-Visner MC, Christensen RD. Platelet reference ranges for neonates, defined using data from over 47,000 patients in a multihospital healthcare system. *J Perinatol.* 2009;29:130–136.)

more pronounced in preterm infants (Sitaru et al., 2005; Ucar et al., 2005). Platelet aggregation studies demonstrated that platelets from neonatal (full-term) cord blood were less responsive than adult platelets to agonists such as adenosine diphosphate (ADP), epinephrine, collagen, thrombin, and thromboxane analogues (Israels et al., 2003). Similar results were obtained in flow cytometric platelet activation studies, which showed decreased expression of surface activation markers in neonatal platelets stimulated with thrombin, ADP, and epinephrine (Israels et al., 2003; Sitaru et al., 2005). Different mechanisms account for the hyporeactivity of neonatal platelets to various agents: (1) the hyporesponsiveness to epinephrine is due to fewer α_2 -adrenergic receptors, the binding sites for epinephrine (Corby and O'Barr, 1981); (2) the reduced response to collagen probably results from impaired calcium mobilization (Gelman et al., 1996); (3) the decreased response to thromboxane results from differences in signaling downstream from the receptor in neonatal platelets (Israels et al., 1997); and (4) the decreased responsiveness to thrombin is related to reduced expression of Protease-Activated Receptor 1 and 4 (PAR 1 and PAR 4) in neonatal platelets (Schlagenhauf et al., 2010).

Surprisingly, while the hypofunctional platelet phenotype in vitro would predict a bleeding tendency, healthy full-term neonates have normal to enhanced primary hemostasis, compared with older children or adults. Bleeding times (BTs) in healthy term neonates are shorter than BTs in adults (Andrew et al., 1990a). Similarly, studies using the platelet function analyzer (PFA-100; an in vitro test of primary hemostasis that measures the time it takes to occlude a small aperture, or closure time [CT]) found that cord blood samples from term neonates exhibited shorter CTs than samples from older children or adults (Israels et al., 2001; Boudewijns et al., 2003). The results of these studies suggest that there is an enhanced platelet/vessel wall interaction in full-term neonates, probably related to their higher hematocrits, higher mean corpuscular volumes, and higher concentrations of von Willebrand factors (vWFs; particularly its ultralong polymers) (Andrew et al., 1990b),

all factors that—combined effectively—counteract the neonatal platelet hyporeactivity. Taken together, the available evidence strongly suggests that the in vitro platelet hyporeactivity of healthy full-term infants is an integral part of a carefully balanced and well-functioning neonatal hemostatic system, rather than a developmental deficiency.

These compensatory mechanisms might be less well developed in preterm infants, whose platelets are also more hyporeactive than those of full-term infants, leading to longer BTs (Del Vecchio et al., 2008) and therefore a less balanced and probably more vulnerable hemostatic system. Specifically, BTs performed on the first day of life were longer in preterm compared with term infants, with neonates less than 33 weeks' gestation exhibiting the longest BTs (Del Vecchio et al., 2008). Saxonhouse et al. (2010) found that PFA-100 CTs from nonthrombocytopenic neonates were inversely correlated to gestational age in both cord blood and neonatal peripheral blood samples obtained on the first day of life. Importantly, however, while these BTs and CTs were longer in preterm compared with term neonates, they were still near or within the normal range for adults, suggesting that healthy preterm neonates also have adequate primary hemostasis. Data regarding how disease processes perturb this delicate system, particularly in the preterm neonate, are lacking.

In vitro studies using flow cytometry or the cone and platelet analyzer showed that the neonatal platelet function improves significantly and nearly normalizes by 10–14 days, even in preterm infants (Sitaru et al., 2005; Ucar et al., 2005; Bednarek et al., 2009). Consistent with this, Del Vecchio et al. (2008) found that, by day 10 of life, all infants had shorter BTs than at birth, and early gestational age-related differences had disappeared. Moreover, little or no further shortening occurred between days 10 and 30. While no causal association has been demonstrated, this period overlaps with the period of highest risk of bleeding among preterm neonatal intensive care unit (NICU) patients: namely, during the first 10 days of life (Stanworth et al., 2009b).

Thrombocytosis in the Neonate

Depending on the pathogenesis, thrombocytosis can be classified as primary (essential) or secondary (reactive). Primary thrombocytosis is a myeloproliferative disorder, caused by monoclonal or polyclonal abnormalities of hematopoietic cells or by abnormalities in TPO biology, leading to uncontrolled platelet production. Patients with primary thrombocytosis might be at risk for bleeding or thrombotic complications, sometimes requiring therapy. However, primary thrombocytosis is extremely rare in children, with an estimated incidence of 1 in 10 million (Dame and Sutor, 2005).

Secondary or reactive thrombocytosis, in contrast, has its highest incidence in neonates and infants. Based on severity, thrombocytosis has been traditionally classified as mild (platelet counts between 500 and $700 \times 10^9/L$), moderate (700 – $900 \times 10^9/L$), severe (900 – $1000 \times 10^9/L$), and extreme thrombocytosis (platelet counts $> 1000 \times 10^9/L$). In a recent study of platelet counts in 47,000 neonates over the first 90 days of life, the 95th percentile upper reference range was as high as $750 \times 10^9/L$, suggesting that mild thrombocytosis might not be pathologic in this population.

The most common causes of reactive thrombocytosis in neonates and children are infections, tissue damage (surgeries, trauma, burns), and anemia (frequently iron deficiency). Reactive thrombocytosis has also been described in association with medications (i.e., corticosteroids), maternal exposure to methadone or psychopharmaceutical drugs, and metabolic diseases, myopathies, or neurofibromatosis. In childhood, reactive thrombocytosis usually does not lead to thromboembolic or hemorrhagic complications, and for that reason therapy with anticoagulants or platelet function inhibitors (i.e., aspirin) is usually not indicated in asymptomatic children, even if the platelet count is greater than $1000 \times 10^9/L$. Individually tailored thrombosis prophylaxis should be considered only in neonates with additional thrombotic risk factors, such as maternal antiphospholipid syndrome or cardiac malformation. In a recent retrospective study of 26 episodes of extreme thrombocytosis (platelet counts $\geq 1000 \times 10^9/L$) in neonates and young infants, 12 patients had had a recent infection, 8 patients had recent surgery (median of 9 and 13 days before the diagnosis of thrombocytosis, respectively), 4 patients were growing premature infants with anemia, 1 patient had methadone withdrawal syndrome, and 1 patient had congenital adrenal hyperplasia. In 20 of the 26 episodes, for which data were available, a reduction in platelet count to less than $1000 \times 10^9/L$ was noted after 7 days (range 1 to 30). No patient had hemorrhagic or thrombotic complications, and only 1 patient was treated with low-dose aspirin because of concomitant complex congenital heart disease generating concerns about potential thrombosis (Wiedmeier et al., 2010).

Thrombocytopenia in the Neonate

Thrombocytopenia in neonates (as in adults) has traditionally been defined as a platelet count of less than $150 \times 10^9/L$ and has been classified as mild (100 – $150 \times 10^9/L$), moderate (50 – $99 \times 10^9/L$), and severe ($<50 \times 10^9/L$). However, consistent with the data by (Wiedmeier et al., 2009), platelet counts in the 100 to $149 \times 10^9/L$ range are somewhat more common among neonates than adults. The incidence of thrombocytopenia in neonates varies significantly, depending on the population studied. Based on the traditional definitions, large studies in unselected populations established an overall incidence of neonatal thrombocytopenia of 0.7% – 0.9% (Dreyfus et al., 1997; Uhrynowska et al., 1997). However, when focusing on neonates admitted to the NICU, the

incidence of thrombocytopenia is much higher, ranging from 18% to 35% (Mehta et al., 1980; Castle et al., 1986; Oren et al., 1994). The incidence of thrombocytopenia is also inversely correlated to the gestational age so that the most immature neonates are the most frequently affected: platelet counts less than $150 \times 10^9/L$ were found at least once during the hospital stay in 70% of infants with a birth weight of less than 1000 g (Christensen et al., 2006).

Approach to the Thrombocytopenic Neonate—Evaluation and Classification

When evaluating a thrombocytopenic neonate, the first step to narrow the differential diagnosis is to classify the thrombocytopenia as either *early onset* (within the first 72 hours of life) or *late onset* (after 72 hours of life) and to determine whether the infant is clinically ill or well. Importantly, infection/sepsis should always be considered near the top of the differential diagnosis (regardless of the time of presentation and the infant's appearance), as any delay in diagnosis and treatment can have life-threatening consequences.

Early-Onset Thrombocytopenia (Fig. 80.2, Box 80.1)

The most frequent cause of early-onset thrombocytopenia in a well-appearing neonate is placental insufficiency, seen in infants born to mothers with pregnancy-induced hypertension/preeclampsia

• BOX 80.1 Classification of Neonatal Thrombocytopenia by Time of Presentation

Early-Onset Thrombocytopenia

Chronic fetal hypoxia (hypertension/preeclampsia, diabetes)—IUGR/SGA
 Immune-mediated thrombocytopenia (NAIT, autoimmune thrombocytopenia)
 Early-onset sepsis (GBS, *Escherichia coli*)
 Congenital viral/parasitic infection (HIV, CMV, toxoplasma, enterovirus)
 Birth asphyxia
 Renal vein thrombosis
 Polycythemia
 Chromosomal anomalies (trisomy 21, 18, 13)
 Congenital thrombocytopenia (TAR, ATRUS syndrome, Wiskott–Aldrich syndrome)
 Congenital leukemia

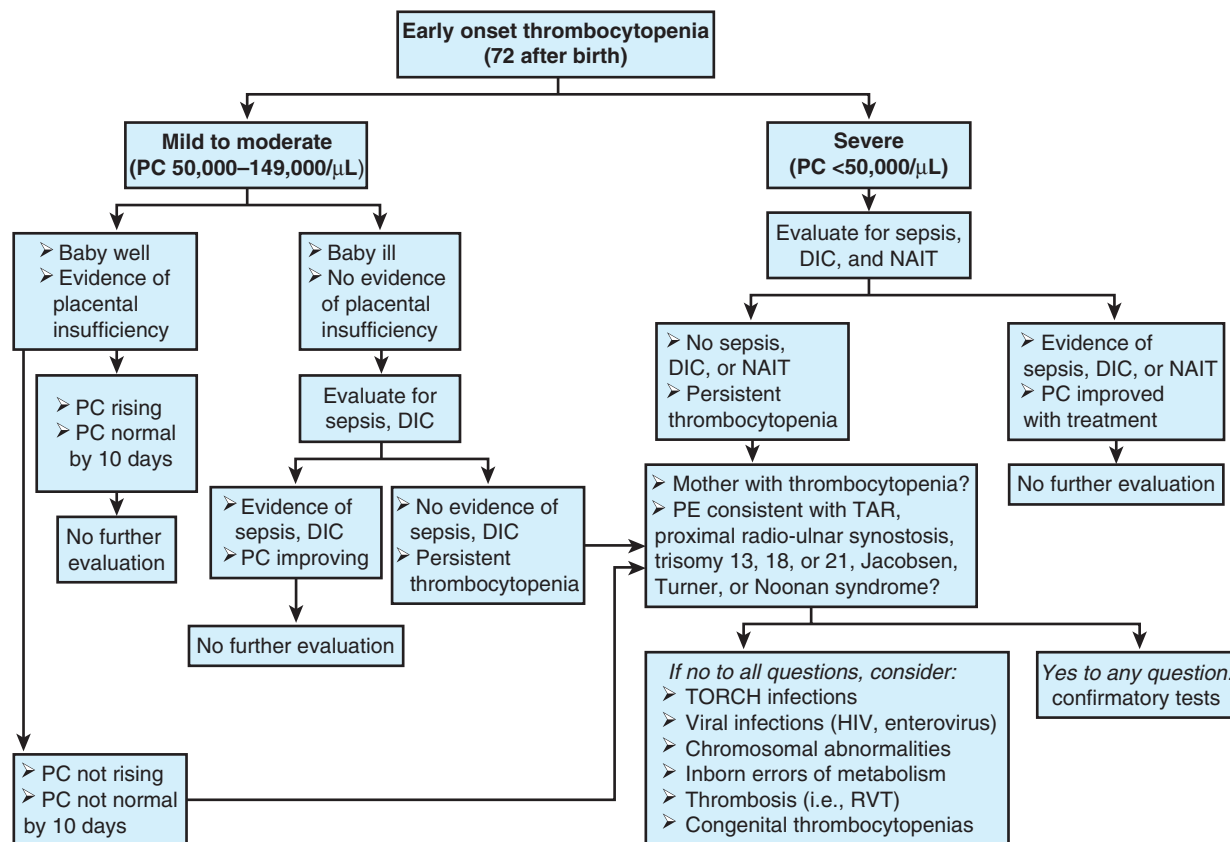

Late-Onset Thrombocytopenia

Late-onset infection/sepsis (bacterial, fungal)
 NEC
 Viral infection (HSV, acquired CMV, enterovirus, adenovirus)
 Thrombosis (catheter related)
 Drug-induced thrombocytopenia (antibiotics, heparin)
 Fanconi anemia

Can Present Both Early and Late

Sepsis/DIC
 Inborn errors of metabolism (Gaucher disease, methylmalonic acidemia)
 Kasabach–Merritt syndrome

ATRUS, Amegakaryocytic thrombocytopenia with proximal radio-ulnar synostosis; CMV, cytomegalovirus; DIC, disseminated intravascular coagulation; GBS, group B streptococcus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; IUGR, intrauterine growth restriction; NAIT, neonatal alloimmune thrombocytopenia; NEC, necrotizing enterocolitis; SGA, small for gestational age; TAR, thrombocytopenia-absent radius syndrome.

• **Fig. 80.2** Guidelines for the evaluation of neonates with early-onset thrombocytopenia (≤ 72 hours of life). DIC, Disseminated intravascular coagulation; HIV, human immunodeficiency virus; NAIT, neonatal alloimmune thrombocytopenia; PC, platelet count; PE, physical examination; RVT, renal vein thrombosis; TAR, thrombocytopenia-absent radius syndrome; TORCH, Toxoplasmosis, Other, Rubella, Cytomegalovirus, Herpes simplex virus infection complex. (Adapted from Deschmann E, Saxonhouse M, Sola-Visner M. Chapter 47: Thrombocytopenia. In: Eichenwald EC, Hansen AR, Martin CR, Stark AR, eds. *Cloherly and Stark's Manual of Neonatal Care*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2016:630–640.)

and in those with intrauterine growth restriction (Murray and Roberts, 1996; Murray et al., 1998). This thrombocytopenia is always mild to moderate, presents immediately or shortly after birth, and resolves within 7 to 10 days. In a recent large cohort study, approximately one-third of small for gestational age (SGA) infants had thrombocytopenia ($<150 \times 10^9/L$) during the first week of life, compared with only 10% of non-SGA-matched infants. This type of thrombocytopenia was associated with low mortality (2%), as long as there was no identified cause for the SGA other than placental insufficiency (i.e., genetic syndrome or congenital infection) (Christensen et al., 2015). If an SGA otherwise nondysmorphic infant with mild to moderate thrombocytopenia remains clinically stable and the platelet count normalizes within 10 days, no further evaluation is necessary. However, if the thrombocytopenia becomes severe and/or persists for greater than 10 days, further investigation is indicated.

Severe early-onset thrombocytopenia in an otherwise healthy infant should trigger suspicion for an immune-mediated thrombocytopenia, either autoimmune (if the mother is also thrombocytopenic) or alloimmune (if the mother has a normal platelet count). These varieties of thrombocytopenia are discussed in detail below. Early-onset thrombocytopenia of any severity in an *ill-appearing* term or preterm neonate should prompt evaluation for sepsis, congenital viral or parasitic infections, or disseminated

intravascular coagulation (DIC). DIC is most frequently associated with sepsis but can also be secondary to birth asphyxia (Suzuki and Morishita, 1998).

In addition to these considerations, the affected neonate should be carefully examined for any radial and thumb abnormalities (suggestive of thrombocytopenia-absent radii [TAR] syndrome, amegakaryocytic thrombocytopenia with radio-ulnar synostosis, or Fanconi anemia). The inability to rotate the forearm on physical examination, in the presence of severe early-onset thrombocytopenia, suggests the rare diagnosis of congenital amegakaryocytic thrombocytopenia with proximal radio-ulnar synostosis (ATRUS). Dysmorphic features on physical examination should warrant investigation for other genetic disorders associated with early-onset thrombocytopenia: most commonly, trisomy 21, trisomy 18, trisomy 13, Turner syndrome, Noonan syndrome, and Jacobsen syndrome.

The presence of hepatomegaly and/or splenomegaly is suggestive of viral infection, although it can also be seen in hemophagocytic syndrome and liver failure from different etiologies (i.e., hemochromatosis). Other diagnoses, such as renal vein thrombosis, Kasabach–Merritt syndrome, and inborn errors of metabolism (mainly propionic acidemia and methylmalonic acidemia) should be considered and evaluated for based on specific clinical indications (i.e., hematuria in renal vein thrombosis, presence of a vascular tumor in Kasabach–Merritt syndrome).

Late-Onset Thrombocytopenia (Fig. 80.3, Box 80.1)

The most common causes of thrombocytopenia of any severity presenting after 72 hours of life are sepsis (bacterial or fungal) and necrotizing enterocolitis (NEC). Affected infants are usually ill appearing and have other signs suggestive of sepsis and/or NEC. However, it is important to keep in mind that *thrombocytopenia can be the first presenting sign of these processes and can precede clinical deterioration*. Appropriate treatment (i.e., antibiotics, supportive respiratory and cardiovascular care, bowel rest in case of NEC, and surgery in case of surgical NEC) usually improves the platelet count in 1 to 2 weeks, although in some infants the thrombocytopenia persists for several weeks. The reasons underlying this prolonged thrombocytopenia are unclear.

If bacterial/fungal sepsis and NEC are ruled out, viral infections such as herpes simplex virus (HSV), cytomegalovirus (CMV), or enterovirus should be considered. These viral infections are frequently accompanied by abnormal liver enzymes. If the infant has or has recently had a central venous or arterial catheter, thromboses should be part of the differential diagnosis, although they only cause thrombocytopenia if the thrombus is enlarging or is infected. Finally, drug-induced thrombocytopenia is rare in neonates but should be considered if the infant is clinically well, other potential etiologies have been ruled out, and he/she is receiving heparin, antibiotics (penicillins, cephalosporins, metronidazole, vancomycin, or rifampin), indomethacin, famotidine, cimetidine, phenobarbital, or phenytoin, among others (Aster and Bougie, 2007; Aster et al., 2009). Other less common causes of late-onset thrombocytopenia include inborn errors of metabolism and Fanconi anemia (rare).

Novel tools to evaluate platelet production, which aid in the evaluation of thrombocytopenia of unclear etiology, have been recently developed and are likely to become widely available to clinicians in the near future. Among those, the immature platelet

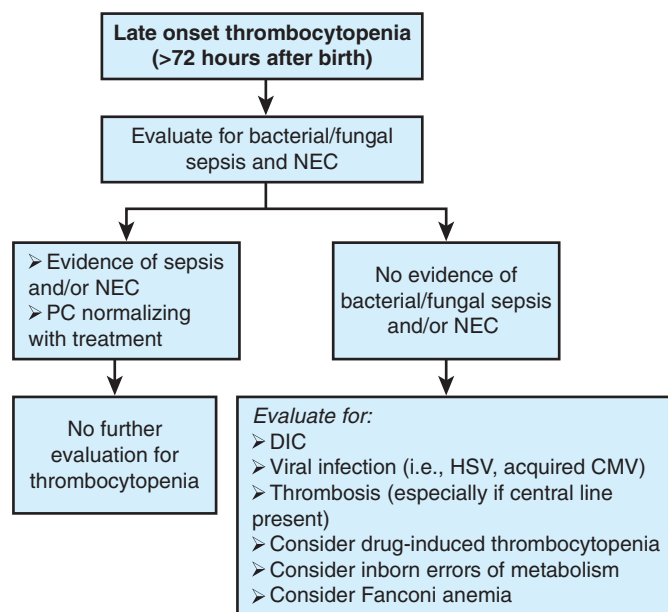

fraction (IPF) measures the percentage of newly released platelets (platelet age <24 hours). The IPF can be measured in a standard hematologic cell counter (Sysmex XE-2100 Automated Hematology System, Sysmex Corporation, Kobe, Japan) as part of the complete cell count and can help differentiate thrombocytopenias associated with decreased platelet production from those with increased platelet destruction, in a manner similar to the use of reticulocyte counts to evaluate anemia (Abe et al., 2006). Thus an elevated IPF would suggest platelet consumption (as in neonatal alloimmune thrombocytopenia [NAIT] or DIC), while a decreased IPF would be consistent with a hyporegenerative thrombocytopenia, as in bone marrow suppression or failure. Reference intervals for immature platelet fraction percentage (IPF%) and absolute immature platelet fraction (A-IPF) have been evaluated by Ko et al. (2013) in a large number of healthy adult individuals and in full-term umbilical cord blood samples (Table 80.1), as well as in nonthrombocytopenic NICU patients by Cremer et al. (2010) (IPF% = $4.1 \pm 1.8\%$; A-IPF = $9.5 \pm 3.8 \times 10^9/L$). Notably, reference ranges for IPF in neonates are higher compared with adults and children (Strauss et al., 2011; Ko et al., 2013). Recent studies have shown the usefulness of the IPF to evaluate mechanisms of thrombocytopenia and to predict platelet recovery in neonates (Cremer et al., 2009, 2010). In patients with NEC and severe thrombocytopenia, a low absolute

IPF has been associated with a poor prognosis and high mortality. The IPF is also particularly helpful to guide the diagnostic evaluation of infants with thrombocytopenia of unclear etiology and can help differentiate rare congenital thrombocytopenias (usually low) from NAIT (usually elevated).

Immune Thrombocytopenia

Immune thrombocytopenia occurs because of the passive transfer of antibodies from the maternal to the fetal circulation. There are two distinct types of immune-mediated thrombocytopenia: (1) NAIT and (2) autoimmune thrombocytopenia. In NAIT, the antibody is produced in the mother against a specific human platelet antigen (HPA) present in the fetus but absent in the mother. The antigen is inherited from the father of the fetus.

The antigens responsible for NAIT are results of single nucleotide polymorphisms in the gene encoding any of the main glycoproteins located on the platelet surface, particularly glycoprotein (GP)IIb/IIIa. The first platelet antigen was identified by van Loghem et al. (1959) and was designated Zw-a (later PLA1). The initial nomenclature for these antigens came from the name of the patients, leading to confusion in the field. In 1990, a simplified system for HPA nomenclature was described, in which each antigen was given an HPA number (von dem Borne and Decary, 1990). Antigens were numbered chronologically, according to the date of their initial report. The biallelic antigens were given an alphabetic designation of “a” or “b” in the order of their frequency (higher frequency for “a”). Thus the Zw-a/PLA1 antigen was renamed HPA-1, with its two serologic forms designated as HPA-1a for the common form and HPA-1b for the less common form (the latter corresponding to PLA2). Sixteen HPA antigens have been identified so far. The frequency of each antigen varies within ethnic groups: in whites, antibodies to HPA-1a are the major cause of NAIT, followed by HPA-5a and, less frequently, HPA-9b, HPA-3a and HPA-3b, and HPA-15. Antibodies to HPA-4b are the predominant cause of NAIT in the Japanese population (Mueller-Eckhardt et al., 1994).

The anti-HPA antibody produced in the maternal serum crosses the placenta and reaches the fetal circulation, leading to platelet destruction, apoptosis of early megakaryocyte progenitors (therefore decreased platelet production) (Liu et al., 2015), and thrombocytopenia. In autoimmune thrombocytopenia, the antibody is directed against an antigen on the mother's own platelets (autoantibody) as well as on the infant's platelets. The maternal autoantibody also crosses the placenta (both passively and actively transported), resulting in destruction of fetal platelets and thrombocytopenia.

Neonatal Alloimmune Thrombocytopenia

NAIT is the most common underlying cause of early-onset, severe thrombocytopenia, with an incidence among live born neonates of 0.5–1.5 per 1000 births (Bertrand et al., 2011). The true incidence of the disease is likely higher, however, since the milder cases might go undetected and the most severe cases lead to intrauterine death. Intrauterine death or intracranial hemorrhage (ICH) may occur as early as at 14 to 16 weeks' gestation, resulting in a relatively high incidence of intrauterine ICH (>10%) (Bertrand et al., 2011). The overall incidence of ICH (prenatal and postnatal) is particularly high in this population, affecting up to 20% of infants with NAIT and potentially leading to lifelong consequences. ICH may occur during the first pregnancy and has a recurrence risk close to 100% in subsequent pregnancies in the absence of prenatal treatment (Bussel et al., 1997).

NAIT should be considered in any neonate who presents with severe thrombocytopenia at birth or shortly thereafter, particularly in the absence of other risk factors, clinical signs, or abnormalities in the physical examination. In a study of more than 200 neonates with thrombocytopenia, using a *platelet count of less than $50 \times 10^9/L$* in the first day of life as a screening indicator identified 90% of the patients with NAIT (Bussel et al., 2005). Based on this observation, *it is currently recommended that all neonates with platelet counts in this range in the first day of life be screened for NAIT*. In addition, the combination of severe neonatal thrombocytopenia with a parenchymal (rather than intraventricular) ICH is highly suggestive of NAIT.

Laboratory Investigation

When NAIT is suspected, blood should be collected from the mother and father and submitted for testing. The initial antigen screening should include HPA-1, HPA-3, and HPA-5. This evaluation should identify approximately 90% of cases of NAIT. However, if the diagnosis is strongly suspected and the initial evaluation is negative, further testing should be undertaken for HPA-9 and HPA-15 (and HPA-4 if the parents are of Asian descent) (Bussel and Sola-Visner, 2009). If positive, these tests will reveal an antibody in the mother's plasma directed against the specific platelet antigen in the father. If blood cannot be collected from the parents in a timely fashion, neonatal serum may be screened for the presence of antiplatelet antibodies. However, a low antibody concentration in the neonate, coupled with binding of the antibodies to the infant's platelets, can lead to false-negative results. It is still unclear if there is any correlation between the affinity of the antibodies and the severity of disease (Bertrand and Kaplan, 2014). Because of the complexity of testing, evaluations should be performed in an experienced reference laboratory that has a large number of typed controls available for antibody detection and the appropriate DNA-based technology to type multiple antigens. In rare cases, antibodies may be hard to detect in samples drawn at the time of delivery; therefore when the clinical diagnosis is most likely NAIT, follow-up serology tests should be performed.

Brain imaging studies (cranial ultrasound) should be performed as soon as NAIT is suspected, *regardless of the presence or absence of neurologic manifestations*, because findings from these studies will dictate the aggressiveness of the treatment regimen for the affected infant and for the mother's future pregnancies. The clinical course of NAIT is short in most cases, often resolving almost entirely within 2 weeks. However, to confirm the diagnosis, it is imperative to follow the platelet count frequently until a normal count is achieved.

Management

The management of NAIT differs, depending on the specific clinical scenario: (1) suspected NAIT (unknown pregnancy); (2) known case of NAIT; and (3) prenatal management of pregnant woman with previous history of NAIT.

Management of the Neonate With Suspected Neonatal Alloimmune Thrombocytopenia (Pregnancy Unknown to the Mother)

Based on recent data demonstrating that a large proportion of infants with NAIT respond to random donor platelet transfusions, this is now considered the first line of therapy for infants in whom NAIT is suspected (Kiefel et al., 2006). If the patient is clinically stable and does not have an ICH, platelets are usually given when the platelet count is less than $30 \times 10^9/L$, although this is arbitrary. In the case of a preterm infant, or a clinically unstable infant (i.e.,

TABLE 80.2 Proposed Platelet Transfusion Recommendation

| Platelet Count ($\times 10^3/\mu\text{L}$) | Recommendations |
|---|--|
| <30 | <i>Transfuse all</i> |
| 30–49 | <i>Transfuse if:</i> <ul style="list-style-type: none"> • BW <1500 g and ≤ 7 days old • Clinically unstable • Recent diagnosis of NEC • Concurrent coagulopathy • Recent major hemorrhage (i.e., grade 3 or 4 IVH) • Prior to surgical procedure • Postoperative period (72 hours) |
| 50–100 | <i>Transfuse if:</i> <ul style="list-style-type: none"> • Active bleeding • NAIT with intracranial hemorrhage • Before and after neurosurgical procedures |

BW, Birth weight; IVH, intraventricular hemorrhage; NAIT, neonatal alloimmune thrombocytopenia; NEC, necrotizing enterocolitis.

From Deschmann E, Saxonhouse M, Sola-Visner M. Chapter 47: Thrombocytopenia. In: Eichenwald EC, Hansen AR, Martin CR, Stark AR, eds. *Cloherly and Stark's Manual of Neonatal Care*. 8th ed. Philadelphia, PA: Wolters Kluwer; 2016:630–640.

respiratory distress, infection), a platelet transfusion is usually given when the platelet count falls below $50 \times 10^9/\text{L}$ during the first week of life (Table 80.2). In addition to platelets, if the diagnosis of NAIT is confirmed or strongly suspected, intravenous immune globulin (IVIG) (1 g/kg per day for up to 2 consecutive days) may be administered to increase the patient's own platelets and potentially to protect the transfused platelets (Mueller-Eckhardt et al., 1989). Because in NAIT the platelet count usually falls after birth, IVIG may be given when the platelet count is between 30 and $50 \times 10^9/\text{L}$ in a stable neonate, to try to prevent a further drop.

If the patient has evidence of an ICH, the goal is to maintain a platelet count greater than $100 \times 10^9/\text{L}$. However, this may be challenging in the setting of NAIT. In all of these scenarios, it is important to keep in mind that some infants with NAIT fail to respond to random donor platelets and IVIG. For that reason, the blood bank should be immediately alerted about any infant with suspected NAIT, and arrangements should be made to secure a source of antigen-negative platelets (either from HPA-1b1b and HPA-5a5a donors, which should be compatible in >90% of cases or from the mother) as soon as possible, so they are available if there is no response to the initial therapies. If maternal platelets are used, they need to be concentrated to decrease the amount of antiplatelet antibodies (present in the mother's plasma) infused into the infant. Platelets can also be washed to eliminate the plasma, although this induces more damage to the platelets than concentrating them (Bussel and Sola-Visner, 2009). Of note, in some European countries, HPA-1b1b and HPA-5a5a platelets are maintained in the blood bank inventory and are immediately available for use. In those cases, these are preferable to random donor platelets and/or IVIG and should be the first line of therapy.

Management of the Neonate With Known Neonatal Alloimmune Thrombocytopenia

When a neonate is born to a mother who had a previous pregnancy affected by confirmed NAIT, genotypically matched platelets (e.g., HPA-1b1b platelets) should be available in the blood bank at the

time of delivery and should be the first-line treatment if the infant is thrombocytopenic.

Management of Pregnant Women With Previous History of Neonatal Alloimmune Thrombocytopenia

Mothers who delivered an infant with NAIT should be followed in high-risk obstetric clinics during all future pregnancies as the reoccurrence rate is high, reaching 100% if the father is homozygous dominant for the causative HPA. However, in all cases fetal genetic testing should be performed. Recently, noninvasive methods have become available through cell-free DNA testing from the mother's plasma. The intensity of prenatal treatment will be based on the severity of the thrombocytopenia and the presence or absence of ICH in the previously affected fetus. This is particularly important to assess the risk of developing an ICH in the current pregnancy and to minimize this risk. Current recommendations involve maternal treatment with IVIG (0.5–2 g/kg per week) \pm steroids (0.5–1 mg/kg per day prednisone), starting at 12 or at 20 to 26 weeks' gestation, depending on whether the previously affected fetus suffered an ICH and if so at what time during pregnancy (Bussel and Sola-Visner, 2009). Most recent studies showed that the combination of IVIG and steroids is the most efficient treatment (Bertrand et al., 2011). Regarding mode of delivery, elective cesarean section is recommended in most countries, regardless of ICH status in the previous and current fetus, to avoid ICH (Bertrand and Kaplan, 2014).

Autoimmune Thrombocytopenia

The diagnosis of neonatal autoimmune thrombocytopenia should be considered in any neonate who has early-onset thrombocytopenia and a maternal history of either immune thrombocytopenic purpura (ITP) or an autoimmune disease (with or without thrombocytopenia). A retrospective study of obstetric patients who had ITP (including a high number of mothers who had thrombocytopenia during their pregnancies) demonstrated a relatively high incidence of affected babies: 25% of neonates had thrombocytopenia at birth; the thrombocytopenia was severe in 9%, and 15% received treatment for it (Webert et al., 2003). Other large studies confirmed an incidence of severe neonatal thrombocytopenia in this population ranging from 8.9% to 14.7%, with ICH occurring in 0%–1.5% of affected neonates (Kaplan et al., 1990; Samuels et al., 1990; Burrows and Kelton, 1993). Based on these data, we recommend that all neonates born to mothers who have autoimmune diseases undergo a screening platelet count at or shortly after birth. If the platelet count is normal, no further evaluation is necessary. If the neonate has mild thrombocytopenia, however, the platelet count should be repeated in 2 to 3 days, since this type of thrombocytopenia usually reaches the nadir between days 2 and 5 after birth. If the platelet count is less than $30 \times 10^9/\text{L}$, IVIG (1 g/kg, repeated if necessary) is the first line of therapy. Random donor platelets, in addition to IVIG, should be provided if the neonate has evidence of active bleeding, although some authors give them in addition to IVIG when the platelet count is less than $30 \times 10^9/\text{L}$ and provide IVIG alone for platelet counts between 30 and $50 \times 10^9/\text{L}$. Cranial imaging (cranial ultrasound) should be obtained in all infants with platelet counts less than $50 \times 10^9/\text{L}$, to evaluate for ICH. Importantly, neonatal thrombocytopenia secondary to maternal ITP may last for weeks to months (unlike NAIT, which usually resolves within 2 weeks) and requires long-term monitoring and sometimes a second dose of IVIG at 4 to 6 weeks of life. Recently, it has been reported that the transfer of antiplatelet

antibodies (immunoglobulin A type) from mothers with ITP through breastfeeding can be associated with persistent neonatal thrombocytopenia (Hauschner et al., 2015).

Maternal Management

Even if the mother has severe ITP, it appears that fetal hemorrhage in utero is very rare, compared with the small but definite risk of such hemorrhage in alloimmune thrombocytopenia. Consequently, treatment of ITP during pregnancy and delivery is mostly based on the risk of maternal hemorrhage (Provan et al., 2010). A small prospective randomized trial of low-dose betamethasone (1.5 mg/day orally) failed to prevent thrombocytopenia in newborns (Christiaens et al., 1990). IVIG given prenatally to the mother with ITP has also not been clearly shown to affect the fetal platelet count.

There is in general little correlation between fetal platelet counts and maternal platelet counts, platelet antibody levels, or history of maternal splenectomy. Attempts to measure the fetal platelet count before delivery are not recommended, because of the risk associated with such attempts. The only reliable predictive measure of neonatal thrombocytopenia in a mother with ITP has been found to be a history of neonatal thrombocytopenia in previous pregnancy (Hachisuga et al., 2014). In regard to the mode of delivery, there is no evidence that cesarean section is safer for the fetus with thrombocytopenia than uncomplicated vaginal delivery. Given this fact, combined with the difficulty predicting severe thrombocytopenia in neonates and the very low risk of serious hemorrhage, the 2010 International Consensus Report on the Investigation and Management of Primary Immune Thrombocytopenia concluded that the mode of delivery in ITP patients should be determined by purely obstetric indications (Provan et al., 2010). However, interventions that increase the risk of bleeding in the fetus should be avoided, such as vacuum extraction or forceps delivery.

Congenital Thrombocytopenias

Congenital thrombocytopenias are rare conditions that most often present at birth and are therefore classified as early-onset thrombocytopenias. This is a heterogeneous group of diseases, with variable clinical manifestations. Often, but not always, patients with congenital thrombocytopenia have dysmorphic features and associated abnormalities as part of a genetic syndrome. If a neonate presents with radial abnormalities, the differential diagnosis includes TAR syndrome, amegakaryocytic thrombocytopenia with radio-ulnar

synostosis, and Fanconi anemia. Although thrombocytopenia associated with Fanconi anemia almost always presents later (during childhood), few isolated neonatal cases have been reported (Gershanik et al., 1972). In these patients, thumb abnormalities are frequently found, and chromosomal fragility testing is nearly always diagnostic. If the infant has radial abnormalities with normal-appearing thumbs, TAR syndrome should be considered (Hedberg and Lipton, 1988). The platelet count is usually less than $50 \times 10^9/L$, and the white cell count is elevated in greater than 90% of TAR syndrome patients, sometimes exceeding $100 \times 10^9/L$ and mimicking congenital leukemia. Infants that survive the first year of life generally do well, since the platelet count then spontaneously improves to low-normal levels that are maintained through life (Geddis, 2006). The inability to rotate the forearm on physical examination, in the presence of severe early-onset thrombocytopenia, suggests the rare diagnosis of congenital ATRUS. Radiologic examination of the upper extremities in these infants confirms the proximal synostosis of the radial and ulnar bones (Sola et al., 2004). Most (but not all cases) of ATRUS are associated with *Hox-A11* mutations (Thompson and Nguyen, 2000; Horvat-Switzer and Thompson, 2006) and require bone marrow transplantation. Other genetic disorders associated with early-onset thrombocytopenia include trisomy 21, trisomy 18, trisomy 13, Turner syndrome, Noonan syndrome, and Jacobsen syndrome. Cases of Noonan syndrome presenting with mild dysmorphic features and very severe neonatal thrombocytopenia (mimicking congenital amegakaryocytic thrombocytopenia [CAMT]) have been recently described, so genetic testing should be performed in children who present with a CAMT-like picture and no mutations in the *C-Mpl* gene (Christensen et al., 2013).

In nonsyndromic cases of congenital thrombocytopenia, there is usually a history of chronic thrombocytopenia in family members. These conditions belong to a heterogeneous group of diseases, and, because of diverse clinical manifestations and laboratory findings, the diagnosis is challenging. Often the size of the platelets helps in the differential diagnosis (Table 80.3). Myosin heavy chain-9 (MYH-9)-related disorders (May-Hegglin anomaly, Fechner syndrome, Sebastian syndrome) are inherited in autosomal dominant fashion and present with macro thrombocytopenia (Pauzner et al., 2009). Other congenital thrombocytopenias presenting with large platelets include Bernard-Soulier syndrome (with autosomal recessive inheritance) and X-linked macrothrombocytopenia. Wiskott-Aldrich syndrome, in contrast, should be suspected in male neonates with severe thrombocytopenia and small platelets

TABLE 80.3 Classification of Congenital Thrombocytopenias by Platelet Size

| Small Platelets | Normal-Sized Platelets | Large Platelets |
|---|---|--|
| Wiskott-Aldrich syndrome (X-linked microthrombocytopenia) | CAMT | MYH-9-associated thrombocytopenia (May-Hegglin anomaly, Sebastian syndrome, Fechtner syndrome, Epstein syndrome) |
| | TAR syndrome | Bernard-Soulier syndrome |
| | Thrombocytopenia associated with trisomies (13, 18, 21) | X-linked macrothrombocytopenia |
| | | Paris-Trousseau syndrome |
| | | Gray platelet syndrome |

CAMT, Congenital amegakaryocytic thrombocytopenia; MYH-9, myosin heavy chain-9; TAR, thrombocytopenia-absent radius.

(≤ 7 femtoliter), particularly if they develop eczema. The diagnosis of CAMT is challenging as it presents with normal-sized platelets and may not be diagnosed in the newborn period (when it is usually confused with alloimmune thrombocytopenia) because of the lack of other clinical features. A summary of congenital thrombocytopenias and their associated features is provided in Table 80.4 (Smock and Perkins, 2014). These conditions are often paired with platelet dysfunction as well.

The outcomes for patients with congenital thrombocytopenia are variable and depend on the specific disorders. Patients with CAMT often develop bone marrow failure and pancytopenia and require bone marrow transplant. The thrombocytopenia in TAR patients is severe at birth but improves over time, often reaching platelet counts greater than $100 \times 10^9/L$. The hematologic outcome of MYH-9-related disorders is good, although patients frequently develop nephritis, hearing loss, and cataracts later in life.

Management of Neonatal Thrombocytopenia

Platelet Transfusions in the Neonatal Intensive Care Unit

Platelet transfusion is the primary modality of treatment for neonatal thrombocytopenia, but there is lack of consensus regarding platelet transfusion thresholds. Recent studies have shown that there is great variability in neonatal transfusion practices in the United States and worldwide (Kahn et al., 2003; Josephson et al., 2009; Stanworth et al., 2009b; Cremer et al., 2011). To a large extent, this is attributable to the absence of scientific evidence in the field, the high incidence of bleeding in this population, and the known platelet hyporeactivity of neonates. Generally, neonates are transfused at higher platelet counts than older children and adults, and thus platelet transfusions are a frequent intervention in the NICU. Despite the high frequency of transfusions, only one randomized trial has compared different platelet transfusion thresholds in neonates. This trial was limited to VLBW infants in the first week of life and excluded patients with severe thrombocytopenia (platelet counts $< 50 \times 10^9/L$) (Andrew et al., 1993). The investigators found no differences in the incidence or severity of intraventricular hemorrhages (IVHs) between a group of neonates transfused for any platelet count less than $150 \times 10^9/L$ and a group transfused only for counts less than $60 \times 10^9/L$. Based on these findings, the investigators concluded that transfusing VLBW infants with platelet counts greater than $60 \times 10^9/L$ does not reduce the risk of IVH. In the contemporary prospective multicenter observational Platelet for Neonatal Transfusion-study 1 (PlaNeT-1), platelet transfusions were administered at a median platelet count of $27 \times 10^9/L$. In a secondary analysis, the temporal association between platelet transfusions and minor bleeding was assessed. This analysis showed that neonates had 21% fewer bleeding events during the 12 hours following a platelet transfusion, compared with the 12 hours before the transfusion (Muthukumar et al., 2012). However, these findings should be interpreted with caution, partly because of the study design (observational study being prone to confounders and lacking a control group) and because these results were part of a secondary analysis. A more recent study by von Lindern et al. (2011) compared bleeding outcomes in an NICU that used liberal transfusion thresholds with an NICU that used restrictive transfusion thresholds. The study found no significant differences in bleeding outcomes between these units.

• **Fig. 80.4** Lowest platelet counts in neonates with and without major or minor hemorrhage. Hatched lines indicate group medians; dashed lines represent interquartile ranges (IQRs). The lowest counts before hemorrhage are shown for neonates with minor or major hemorrhage, and the lowest counts during the thrombocytopenic episode are presented for neonates with no bleeding. (Adapted from Stanworth SJ, Clarke P, Watts T, et al. Prospective, observational study of outcomes in neonates with severe thrombocytopenia. *Pediatrics*. 2009;124:e826–e834.)

The relationship between degree of thrombocytopenia and bleeding risk has been assessed in a number of neonatal studies (Andrew et al., 1987; Stanworth et al., 2009b). The PlaNeT-1 study found that 9% of thrombocytopenic neonates experienced clinically significant bleeding (most commonly intracranial): 87% of these hemorrhages occurred during the first 2 weeks of life, and 87% were in neonates less than 28 weeks' gestation. Importantly, nadir platelet counts were similar in infants who experienced clinically significant bleeding compared with those with no or only minor bleeding (Fig. 80.4). A secondary analysis looking at all bleeding events (minor as well as clinically significant) found that a lower nadir platelet count was associated with only a slightly increased number of bleeding events. In that study, the strongest predictors of bleeding were gestational age less than 28 weeks, postnatal age less than 10 days, and a diagnosis of NEC (Muthukumar et al., 2012), suggesting that factors other than the platelet count are the most important determinants of bleeding risk. Consistently, a recent study by Sparger et al. (2016) found that the risk of IVH was higher in VLBW infants with thrombocytopenia in the first week of life, compared with nonthrombocytopenic neonates, but there was no correlation between degree of thrombocytopenia and IVH risk. Furthermore, platelet transfusions (which in this study were mostly given for platelet counts between 50 and $100 \times 10^9/L$) did not reduce the risk of IVH, further supporting the lack of efficacy of platelet transfusions given at these platelet counts to prevent IVH. Based on this limited evidence, coming mostly from observational studies, we currently propose administering platelet transfusions to neonates according to the criteria shown in Table 80.2.

There is more consensus in regard to the platelet product that should be transfused. Most experts agree that neonates should receive 10–15 mL/kg of a standard platelet suspension, either a platelet concentrate (“random-donor platelets”) or apheresis platelets. Each random-donor platelet unit has approximately 50 mL of volume and contains approximately 10×10^9 platelets per 10 mL (Strauss, 2000). There is no need to pool more than one random-donor unit for a neonatal transfusion, a practice that only increases donor exposures and induces platelet activation, without any benefit. Two additional important considerations in neonatology are the

**TABLE
80.4****Genetic and Clinical Characteristics of Congenital Thrombocytopenias**

| Disease | Mode of Inheritance | Degree of Thrombocytopenia | Platelet Size | Other Clinical/Pathologic Features | Genetic Defect |
|--|---------------------|---|---|---|---|
| Congenital amegakaryocytic thrombocytopenia | AR | Severe—type 1 Mild to moderate—type 2 | Normal | Absence of megakaryocytes in marrow Develop bone marrow failure/pancytopenia, markedly elevated TPO levels | Mutations in <i>MPL</i> gene |
| TAR | AR | Severe at birth but usually less severe with age | Normal | Congenital malformations including bilateral absent radii, skeletal and cardiac abnormalities, often have cow's milk intolerance, elevated TPO levels. Decreased to absent megakaryocytes in marrow at birth, low to normal numbers later in life | Unknown. Mutation in exon junction complex subunit <i>RBM8A</i> gene. Micro deletion of chromosome 1q21.1 (not causative) |
| Bernard–Soulier syndrome | AR | Mild | Large | Abnormal platelet function. Decreased GPIb complex on platelets. Marrow has normal to slightly increased normal megakaryocytes. | Mutations in <i>GP1BA</i> , <i>GP1BB</i> , or <i>GP9</i> genes |
| <i>MYH9</i> -related disorders May–Hegglin anomaly Sebastian syndrome Fechtner syndrome Epstein syndrome | AD | Mild–moderate Mild–moderate Mild–moderate Mild–moderate Mild–moderate | Large Large Large Large Large | All will have Dohle-like bodies in myeloid cells. Nephritis, hearing loss, and cataracts Nephritis and hearing loss | Mutation in <i>MYH9</i> gene on 22q12.3-13.1, variable penetrance |
| Familial platelet disorder with predisposition to acute myelogenous leukemia | AD | Moderate | Normal | Predisposition to develop AML or MDS Abnormal platelet aggregation/prolonged bleeding times Abnormal platelet function Decreased megakaryocytes in marrow | Heterozygous <i>RUNX1</i> mutation on 8q22 |
| Mediterranean macrothrombocytopenia | AD | Mild | Large | Seen in patients from Italy and Balkan peninsula. May represent carrier state for Bernard–Soulier syndrome | Mutation in <i>GP1A</i> gene on chromosome 17 |
| Paris–Trousseau syndrome | AD | Moderate to severe at birth but improve with age to near normal | Large | Congenital abnormalities including psychomotor retardation, trigonocephaly, facial dysmorphism, and cardiac abnormalities. Dysmegakaryopoiesis with many micromegakaryocytes and abnormal α -granules | Mutation in <i>FLI1</i> gene on 11q23.3 |
| Gray platelet syndrome | AR | Mild to moderate | Large | Develop myelofibrosis and splenomegaly. Platelets lack α -granules and appear agranular and gray. Variable bleeding | Unknown. Mutations in <i>NBEAL2</i> gene in AR disease |
| X-linked microthrombocytopenia (Wiskott–Aldrich syndrome) | X | Variable—usually mild to moderate | Small | Normal to increased megakaryocytes. Splenic destruction thought to cause small platelet size and thrombocytopenia. Patients may have eczema and T-cell lymphopenia. Increased incidence of autoimmune disorders and lymphoma | Mutation in <i>WAS</i> gene at Xp11.4-p11.21 |
| X-linked thrombocytopenia with dyserythropoiesis (<i>GATA1</i>) | X | Moderate to severe | Large to normal | Usually have bleeding and bruising with abnormal platelet function. Anemia. Hypercellular marrow with dysplastic erythroid and megakaryocytic precursors | Mutation in <i>GATA1</i> gene at Xp11.23 |

AD, Autosomal dominant; AML, acute myelogenous leukemia; AR, autosomal recessive; GPIb, glycoprotein Ib; MDS, myelodysplastic syndrome; TAR, thrombocytopenia-absent radius; TPO, thrombopoietin; X, X-linked.

From Smock KJ, Perkins SL. Thrombocytopenia: an update. *Int J Lab Hematol*. 2014;36:269–278.

prevention of transfusion-transmitted CMV infections and graft-versus-host disease (GVHD). Most blood banks provide either CMV-negative or leuko-reduced products to neonates, both of which significantly reduce (but do not completely eliminate) the risk of transfusion-transmitted CMV. Transfusion of CMV-negative and leuko-reduced blood products completely prevented transmission of CMV to VLBW infants in a recent study (Josephson et al., 2014). GVHD is prevented by irradiating cellular blood products before transfusion. Of note, most neonatal cases of GVHD have been reported in neonates with underlying immunodeficiencies, receiving intrauterine or large-volume transfusions (i.e., double exchange transfusions), or receiving blood products from a first-degree relative. Thus these are all absolute indications for irradiating blood products (Strauss, 2000).

When making platelet transfusion decisions, it is important for neonatologists to be aware of the risks associated with these transfusions. In the case of platelet suspensions, the risk of bacterial contamination is higher than the combined risk of all viral infections for which platelets are routinely tested. This is because platelet suspensions are stored in the blood bank at room temperature for up to 5 days, which increases the risk of bacterial growth. In addition, platelet transfusions can induce transfusion-associated lung injury (TRALI), a process characterized by the onset of hypoxemia and bilateral pulmonary infiltrates within 6 hours of a transfusion (Goldman et al., 2005). Given that neonates have frequent episodes of respiratory decompensation due to variable causes, TRALI is likely to be under-recognized in the NICU. Several publications have also shown a strong association between the number of platelet transfusions and the mortality rate among NICU patients (Del Vecchio et al., 2001; Garcia et al., 2001; Baer et al., 2007; Stanworth et al., 2009a). It is unclear from these studies whether this association simply reflects sicker patients receiving more platelets or whether platelet transfusions adversely affect outcomes. Nevertheless, while we await data from well-designed randomized controlled studies (the ongoing PlaNeT-2 trial is comparing 25 vs $50 \times 10^9/L$ as platelet transfusion thresholds for neonates) (Curley et al., 2014), neonatologists should undertake platelet transfusions thoughtfully, carefully balancing the risks and benefits in each individual patient.

Alternative Tests to Guide Platelet Transfusions

While, currently, platelet transfusions are administered on the basis of platelet counts or platelet mass (platelet count \times platelet volume), the evidence strongly suggests that factors other than the degree of thrombocytopenia determine the bleeding risk. Thus larger studies are needed to better characterize the platelet function and the hemostatic profile of preterm infants and their changes over time and in response to illness. Along these lines, it will also be important to develop and validate tests that can be used in preterm infants and that incorporate both platelet count and function to evaluate hemostasis, rather than individual platelet factors alone.

The PFA-100 is an *in vitro* test of primary hemostasis that provides a quantitative measurement of platelet adhesion, activation, and aggregation in whole blood (Kundu et al., 1995). As PFA-100 CTs represent global measurements of primary hemostasis, they are particularly attractive in neonates, since many factors contribute to their finely balanced hemostatic system. A recent pilot study measuring PFA-100 CTs in thrombocytopenic neonates of various gestational and postnatal ages showed that closure time-adenosine diphosphate (CT-ADP) was a better marker for evaluating neonatal platelet function than closure time-epinephrine (CT-Epi) and identified a threshold effect of platelet counts on CT-ADP: all

infants with platelet counts greater than $90 \times 10^9/L$ had normal CT-ADP, and most infants with platelet counts less than $90 \times 10^9/L$ had normal or minimally prolonged CT-ADP, but a few exhibited significant prolongations (Deschmann et al., 2014). It is unknown whether a prolonged CT-ADP is a better predictor of bleeding risk than the platelet count alone.

Nontransfusal Therapies

While severe thrombocytopenia resolves within 14 days in 80% of affected neonates, in approximately 10% it persists for greater than 30 days (Murray et al., 2002), resulting in multiple platelet transfusions (>20) (Dohner et al., 2009). In 2008, two TPO mimetics, romiplostim and eltrombopag, were approved by the US Food and Drug Administration (FDA) for the treatment of adults with chronic immune thrombocytopenic purpura, and, more recently, eltrombopag was approved for use in other varieties of chronic thrombocytopenia (i.e., chronic hepatitis C, aplastic anemia). In 2015 (Grainger et al., 2015), eltrombopag was approved by the FDA for use in children with symptomatic chronic immune thrombocytopenia. Recent publications have reported the use of eltrombopag in adult and pediatric patients with various hematologic disorders, including inherited thrombocytopenia associated with *MYH-9* mutations (Pecci et al., 2010; Favier et al., 2013), Wiskott–Aldrich syndrome (Gerrits et al., 2015), and aplastic anemia (Olness et al., 2012; Desmond et al., 2014). Thus it is plausible that eltrombopag would also be considered as a therapeutic alternative in neonates, infants, and children in the first year of life with different varieties of thrombocytopenia. Both agents, romiplostim and eltrombopag, begin to raise platelet counts 4 to 6 days after the initiation of the treatment and reach peak platelet counts at 10 to 14 days. Because of these pharmacodynamic characteristics, they would be only appropriate for selected infants with thrombocytopenia severe enough to warrant treatment and expected to last longer than 10 to 14 days. Difficulties in predicting the duration of thrombocytopenia in neonates have hampered the use of any TPO mimetics in neonates and infants less than 12 months old, which so far has been limited to sporadic reports (Christensen et al., 2013). It is likely that only a very small subset of thrombocytopenic neonates would be appropriate candidates for treatment with these medications.

Platelet Function Disorders

Etiology/Pathophysiology

Platelets play a major role in hemostasis, both by supporting the cellular structure for the primary platelet plug and also by providing a phospholipid surface on which the plasma elements involved in coagulation can bind. Thus a decrease in the platelet count and/or poor platelet function can result in bleeding symptoms. Platelet function disorders can be broadly categorized as congenital or acquired.

Most platelet function defects seen in the NICU are acquired and can be due to medications, medical conditions, or medical interventions. The list of medications that can affect platelet function is extensive, but the most common medications resulting in platelet dysfunction include aspirin and other nonsteroidal antiinflammatory drugs (indomethacin and ibuprofen), prostacyclin, certain anti-convulsants (valproic acid in particular), and some antibiotics (beta-lactams). Among the medical disorders associated with platelet dysfunction, the most common and best described is uremia.

Although the exact mechanism by which the platelets are affected is not clear, a prevailing theory is that the accumulation of certain substances associated with uremia disrupts the platelet phospholipid surface. Finally, certain medical procedures are associated with platelet dysfunction, with the most common being the use of extracorporeal circuits (extracorporeal membrane oxygenation, cardiopulmonary bypass, and hemodialysis). Therapeutic hypothermia, currently standard of care for infants with hypoxic–ischemic encephalopathy, also is associated with transient platelet dysfunction (Christensen et al., 2012).

Congenital platelet function disorders occur as a result of defects or deficiencies in any of a multitude of components (functional, structural, and regulatory proteins) required for normal platelet function. The most severe platelet function defects, which can present in neonatal life, result from deficiency or absence in the GPs located on the platelet surface: Bernard–Soulier syndrome, caused by deficiency of GPIb (the vWF receptor), and Glanzmann thrombasthenia, caused by a deficiency of GPIIb/IIIa, the fibrinogen receptor (Nurden and Nurden, 2008). Both have been reported to present with bleeding in neonatal life, although they most frequently present later in childhood.

Most of the other inherited platelet function defects are mild and very rarely present in the newborn period. Secretory platelet disorders have defective platelet granules and cause mild to moderate bleeding. These include δ -storage pool defects (including the common ADP secretion defect and the less common absence of dense bodies associated with Hermansky–Pudlak syndrome) and α -granule defects (gray platelet syndrome). Over the last decade, the availability of better genetic tools has led to the identification of the genetic causes of many of these platelet functional defects (i.e., mutations in *NBEAL2* cause gray platelet syndrome) and of novel mutations associated with platelet dysfunction and bleeding. A thorough review of these disorders is outside of the scope of this chapter, particularly because the degree of bleeding associated with most of these conditions rarely manifests in the neonatal period.

Clinical Presentation

Patients with platelet function disorders present with bleeding signs similar to thrombocytopenia, including mucocutaneous bleeding (nose, mouth, gastrointestinal tract, genitourinary tract) and bruising. The extent, location, and nature of the bruises are generally related to birth trauma and invasive procedures. Bernard–Soulier syndrome patients present with mild thrombocytopenia, giant platelets on the blood smear (macrothrombocytopenia), and mucosal-type bleeding caused by platelet dysfunction. Patients with Bernard–Soulier syndrome have been reported to present as neonates with gastrointestinal bleeding, bleeding after circumcision, and bleeding after cardiac catheterization in a patient with DiGeorge syndrome (Lopez et al., 1998). Glanzmann thrombasthenia is a rare autosomal recessive platelet function disorder, caused by a deficiency or abnormality of GPIIb/IIIa expression on the platelet surface. In neonates, the most common manifestations of Glanzmann thrombasthenia are generalized purpura or bleeding after circumcision, although more serious hemorrhages have also been described (George et al., 1990).

Diagnosis

The diagnosis of platelet function disorders in neonates is problematic, because many of the traditional tests require a large amount of blood (platelet aggregation studies) or lack reference values for

neonates. The traditional assay of platelet function is platelet aggregometry. This assay uses a set concentration of platelet-rich plasma and assesses platelet aggregation via light transmission after addition of a variety of platelet agonists (ADP, epinephrine, ristocetin, arachidonic acid, collagen, and thrombin-related activation peptide). Neonates have reduced platelet aggregation compared with older children and adults (based on cord blood values), and therefore the interpretation of this test in neonates is difficult. The major limitation of platelet aggregometry in neonates has been the large amount of blood required (20–30 mL, depending on the platelet count and how many agonists will be tested). Recently, whole blood aggregometry assays have been developed and are becoming increasingly available. These assays require significantly less blood than traditional platelet aggregometry, thus making them accessible to neonates. However, the lack of neonatal reference ranges has hampered the wider use of aggregometry in this age group.

There are two other tests that can screen for platelet function disorders; however, both have significant limitations. The original screening test is the BT, a test that is difficult to perform, particularly in neonates, and is rarely offered clinically. The PFA-100 is a widely used laboratory assay available in most coagulation laboratories and is a useful screening assay to evaluate for disorders of primary hemostasis. Normal ranges for the PFA-100 have been established in cord blood (Israels, 2009) and more recently in neonatal blood (Saxonhouse et al., 2010). The blood volume required for this test is much less than for aggregometry, and thus it can be used in neonates. Patients with severe platelet function defects, such as Bernard–Soulier syndrome and Glanzmann thrombasthenia, typically have significantly abnormal results. The PFA-100 is also often abnormal in the milder disorders such as the common ADP secretion defects; however, its sensitivity for these disorders is not sufficient to allow such defects to be ruled out if the results are normal. The PFA-100 is also abnormal in patients on aspirin and clopidogrel and ticlopidine (the collagen/ADP cartridge). Neonates on indomethacin, ibuprofen, or certain antibiotics can also have a prolonged PFA-100. The effects of other medications known to affect platelet function are not clear. Thus the PFA-100 is a useful screen for the platelet function defects. However, it cannot be performed when the patient is on certain medications, and it cannot rule out milder platelet function defects.

In general, it is reasonable to start with a complete blood count and a review of the peripheral blood smear. The combination of mild thrombocytopenia and large platelets (macrothrombocytopenia) is suggestive of Bernard–Soulier syndrome, which can be confirmed using flow cytometry to evaluate for the presence of GPIb on the platelet surface. Similarly, GPIIb/IIIa surface expression can be assessed to evaluate for Glanzmann thrombasthenia. This evaluation can be done in a small blood volume and is accurate in neonatal life. Some platelet function defects also lead to easily identifiable ultrastructural changes in the platelets that can be visualized by electron microscopy. In particular, a deficiency or absence of dense bodies (δ -storage pool deficiency) or α -granules (gray platelet syndrome) can be demonstrated by electron microscopy.

More recently, a high-throughput sequencing platform targeting 63 genes relevant for bleeding and platelet disorders was generated, which allows the efficient molecular diagnosis of bleeding and platelet disorders, avoiding the need for multiple sequential tests to narrow the diagnostic possibilities. This DNA-based diagnostic platform will probably become the new approach to patients with suspected inherited platelet function disorders (Simeoni et al., 2016).

Treatment

The management of congenital platelet function defects relies on several medications and platelet transfusions in dire situations when the medications or local measures are ineffective. In acquired conditions, reversal of the condition that led to the platelet dysfunction will reverse the platelet defect, but this is not always possible. In such situations, the approach to management of bleeding is mostly based on platelet transfusions.

Several medications have nonspecific mechanisms whereby they can enhance hemostasis when platelet function is abnormal: these include desmopressin, antifibrinolytic agents, and recombinant activated factor VIIa (rFVIIa). Desmopressin has been demonstrated to improve platelet function in many congenital disorders, in uremia, and during cardiopulmonary bypass. However, desmopressin is generally not used in children less than 2 years of age, because it can lead to vasodilatation, resulting in reductions in blood pressure sufficient to lead to clinical signs, but mostly because it is an analogue of antidiuretic hormone and can induce hyponatremic seizures. Neonates are at a particularly high risk for this complication; thus desmopressin is not recommended in this age group.

rFVIIa was developed for the management of bleeding in patients with hemophilia and inhibitors; however, it has been shown to also be effective for managing severe bleeding in patients with severe platelet function defects. It is licensed in Europe for the management of bleeding in patients with Glanzmann thrombasthenia who are refractory to platelet transfusions. The major risk of rFVIIa is the risk of thrombosis. Thus it is suggested that rFVIIa be used only for patients with severe bleeding in whom standard therapeutic measures have failed. The use of this agent in neonates has been reported, and it appears that neonates are at increased risk for thrombosis from this agent compared with older children (Young et al., 2009). There is no consensus, however, since another study evaluating the risk of thrombotic events associated with rFVIIa use in neonates showed a prevalence of 7.5% in bleeding and/or coagulopathic neonates, although this prevalence was similar in those neonates who received fresh frozen plasma (Puetz et al., 2009). Antifibrinolytic agents might also be helpful, particularly later in life, for epistaxis and menorrhagia.

For severe bleeding that has not responded to the measures just described, a platelet transfusion should be given in order to provide normally functioning platelets. Although most platelet function defects are mild enough that this will never be required, for the

more severe disorders such as Bernard–Soulier syndrome and Glanzmann thrombasthenia, a platelet transfusion may be lifesaving. The risks associated with a platelet transfusion are no different from those for other patients, with one important exception: patients with Bernard–Soulier syndrome and Glanzmann thrombasthenia are at risk for alloimmunization, resulting in the formation of antibodies to GPIb and GPIIb/IIIa, respectively. Once these antibodies develop, future platelet transfusions are likely to be ineffective. Thus it is imperative to withhold platelet transfusions for these patients except in life-threatening hemorrhage, because it may be possible to use this therapy only once in a patient's lifetime. Finally, local measures are extremely important in the management of bleeding.

Neonatal Erythrocyte Disorders

ROBERT D. CHRISTENSEN

KEY POINTS

- Anemia and polycythemia are defined during the neonatal period in accordance with reference intervals appropriate for gestational and postnatal age. Anemia corresponds to a hemoglobin or hematocrit value below the fifth percentile lower reference interval, and polycythemia corresponds to a value above the 95th percentile (sometimes the 97.5th percentile value is used) upper reference interval.
- Anemia in a fetus or neonate can be categorized kinetically as the result of erythropoietic failure, hemorrhage, or hemolysis.
- Polycythemia in a fetus or neonate can be categorized kinetically as the result of increased erythropoiesis in utero (accompanying fetal hypoxia), intravascular fluid contraction, or hypertransfusion.
- Adopting guidelines for preventing and treating neonatal anemia can bring consistency, foster quality improvement research, and reduce costs.

Anemia corresponds to a pathologically low hematocrit (or blood hemoglobin concentration or circulating erythrocyte count), and polycythemia corresponds to a pathologically high value ([Henry and Christensen, 2015a](#)). By convention, anemia is diagnosed in a neonate when the hematocrit, hemoglobin level, or red blood cell (RBC) count falls below the fifth percentile lower reference interval for gestational and postnatal age. In like manner, polycythemia is diagnosed in a neonate when these measures are above the 95th percentile (or 97.5th percentile) upper reference interval. To review this topic, this chapter has been divided into four parts: (1) the reference intervals with which neonatal anemia and neonatal polycythemia are diagnosed, (2) neonatal anemia, (3) neonatal polycythemia, and (4) treatment considerations.

Reference Intervals

Maxwell M. Wintrobe is sometimes referred to as the father of clinical hematology ([Christensen et al., 2016b](#)). Many of his discoveries and inventions in the 1930s and 1940s remain central to modern hematology practice. They include the hematocrit and the RBC indices (mean corpuscular volume [MCV], mean corpuscular hemoglobin [MCH], mean corpuscular hemoglobin concentration [MCHC]). When asked about these, Wintrobe explained his motivation: “I discovered that there were no

reliable normal blood values. What was called ‘normal’ was based on only a few counts that had been made in the nineteenth century. So I proceeded to collect normal blood values. Others elsewhere, also mindful of this deficiency, were beginning to do the same.”

The need for accurate normal ranges exists in modern neonatal hematology. Unlike the case in adult hematology, “reference intervals” are used in neonatology in place of the “normal ranges.” The difference is that reference intervals are constructed from selected clinically performed laboratory tests, not from tests performed on healthy volunteers. To approximate a normal range, the laboratory test results included in a neonatal reference interval data set include results only from patients with minimal disease or with disease not known to be related to the test under consideration ([Henry and Christensen, 2015a](#)). For instance, reference intervals for the hematocrit exclude data from neonates with clinical issues known to affect the hematocrit, such as recipients of RBC transfusions, those with a diagnosis of hemolytic disease, or those who have a diagnosis of anemia or polycythemia.

Reference intervals for hematocrit and hemoglobin level of neonates on the day of birth are shown in [Fig. 81.1](#). Reference intervals for hematocrit and hemoglobin level during the first 28 days after birth are shown in [Fig. 81.2](#). The fall in hemoglobin level and hematocrit during the first few days after birth occurs too rapidly to be explained by reduced RBC production alone and suggests an element of transient, mild, but active hemolysis. The theory of a physiologic hemolysis during the first few days after birth is supported by elevated exhaled carbon monoxide (CO) concentrations during the first week after birth ([Tidmarsh et al., 2014](#)). CO is released when heme is metabolized to bilirubin, and thus the higher exhaled CO levels initially suggest more rapid heme degradation during the first few days ([Christensen et al., 2015b, 2016c](#)). The mechanism responsible for this mild, transient, physiologic hemolysis in neonates and its purposes in nature are under investigation ([Song et al., 2015](#)).

Erythrocyte indices can help categorize anemias. The average size of erythrocytes is reflected by the MCV (measured in femtoliters), and the average amount of hemoglobin per erythrocyte is reflected by the MCH (measured in pictograms). [Fig. 81.3](#) shows the reference intervals for the MCV and MCH on the day of birth according to gestational age ([Christensen et al., 2008](#)). Unlike the MCV and MCH, the concentration of hemoglobin in RBCs (the MCHC) does not change during gestation.

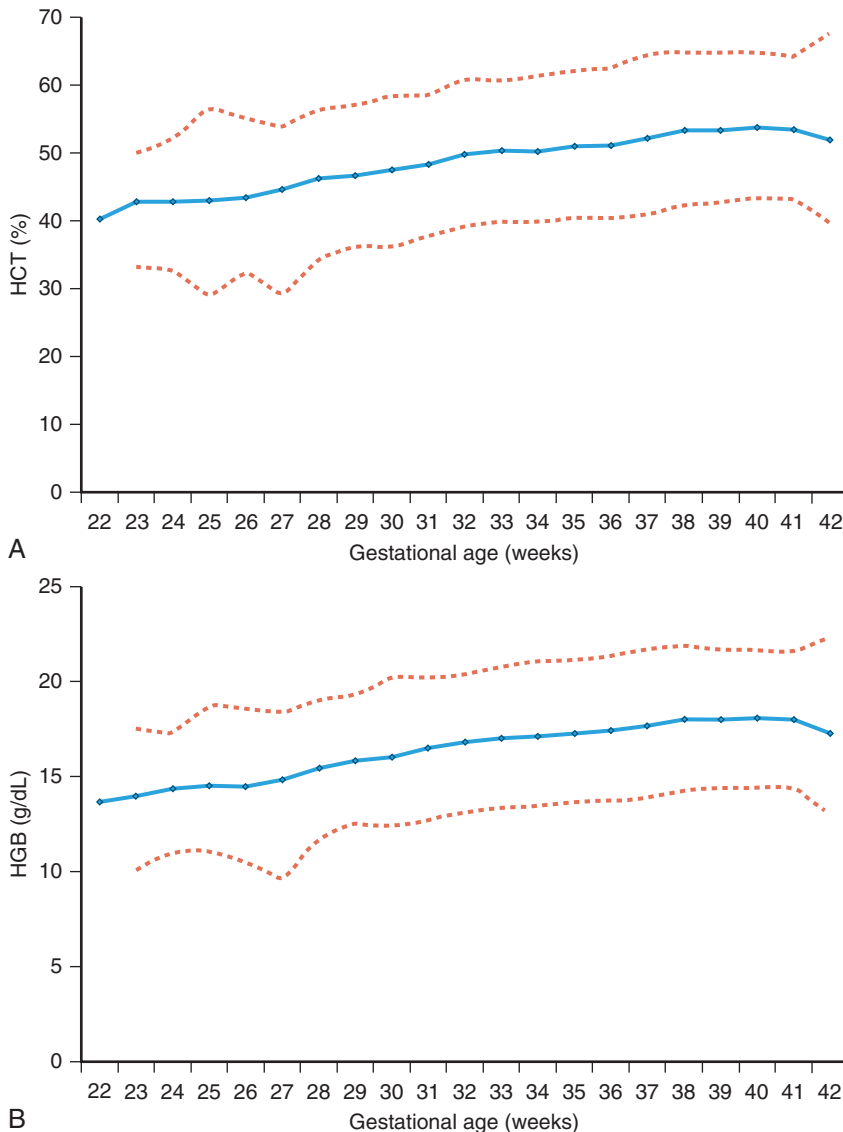

RBC morphology of neonates is characterized by anisocytosis, variation in erythrocyte size (when compared with blood films of adults), and by poikilocytosis, variation in erythrocyte shape. Anisocytosis can be quantified by the RBC distribution width (RDW; %), such that the higher the RDW, the more anisocytosis is present. Reference intervals for RDW during the neonatal period are shown in Fig. 81.4. The poikilocytosis of neonates includes the presence of a few target cells and stomatocytes and schistocytes (Christensen et al., 2014e, 2015d).

Reticulocyte counts and reticulocyte parameters can also be helpful in categorizing anemias (Christensen et al., 2016a). Neonatal reference ranges for the absolute reticulocyte count, the immature reticulocyte fraction, and the reticulocyte hemoglobin content are shown in Fig. 81.5.

Nucleated RBCs are seen regularly on blood smears during the first day of life but are uncommonly seen in the circulation after day 3, unless intermittent or chronic hypoxemia is present (Christensen et al., 2011b). Reference intervals for the number of nucleated RBCs per microliter and reference intervals for the number of nucleated RBCs per 100 leukocytes according to gestational age are shown in Fig. 81.6.

Marrow cellularity in the fetus is relatively high. Erythroid precursors account for 30%–65% of nucleated marrow cells at birth, and myeloid cells account for 45%–75% (Gairdner, 1952). The myeloid-to-erythroid ratio at birth is approximately 1.5:1. Marrow cellularity decreases after birth, attaining a density that is normal for adults by 1 to 3 months. Initially, this decrease in cellularity results from a rapid decline in RBC production. At 1 week of age, erythroid elements account for only 8%–12% of nucleated cells, and the myeloid-to-erythroid ratio exceeds 6:1. The normal adult proportion of myeloid to erythroid precursors is not established until the third month. Both the percentage and the absolute number of lymphocytes increase during the first 2 months, such that by 3 months of age they constitute nearly 50% of marrow nucleated cells. Differential counts of bone marrow aspirates from preterm infants are similar to those of term infants (Christensen, 2000).

In newborns the hemoglobin concentration and hematocrit of capillary blood are 5%–10% higher than those of venous blood (Oettinger and Mills, 1949). The difference between capillary and venous values is greatest at birth and disappears by about 3 months of age. The discrepancy is greatest in preterm infants and

• **Fig. 81.1** Reference intervals for hematocrit (A) and blood hemoglobin concentration (B) on the day of birth. Values are given as a function of gestational age. Dashed lines indicate 5th and 95th percentile reference interval. Solid line indicates mean. *HCT*, Hematocrit; *HGB*, hemoglobin. (From Jopling J, Henry E, Wiedmeier SE, Christensen RD. (From Jopling J, Henry E, Wiedmeier SE, Christensen RD. Reference ranges for hematocrit and blood hemoglobin concentration during the neonatal period: data from a multihospital health care system. *Pediatrics*. 2009;123:e333–e337.)

• **Fig. 81.3** Reference intervals for mean corpuscular volume (A) and mean corpuscular hemoglobin (B) on the day of birth according to gestational age. The *lower line* shows the fifth percentile lower reference interval limit, the *middle line* shows the median values, and the *upper line* shows the 95th percentile upper reference interval limit. *MCH*, Mean corpuscular hemoglobin; *MCV*, mean corpuscular volume. (From Christensen RD, Jopling J, Henry E, Wiedmeier SE. The erythrocyte indices of neonates, defined using data from over 12,000 patients in a multihospital health care system. *J Perinatol*. 2008;28:24–28.)

• **Fig. 81.4** Reference intervals for red blood cell distribution width (RDW) of neonates: (A) RDW on the day of birth, shown by weeks of gestation; (B) RDW over the first 14 days after birth, divided into four gestational-age groups. *D*, Day(s). (From Christensen RD, Yaish HM, Henry E, Bennett ST. Red blood cell distribution width: reference intervals for neonates. *J Matern Fetal Neonatal Med.* 2015;28:883–888)

in those with hypotension, hypovolemia, and acidosis (Linderkamp, 1977).

Measuring the circulating RBC volume in a fetus or neonate is challenging. Mock et al. (2001) used a nonradioactive method based on in vivo dilution of biotinylated RBCs enumerated by flow cytometry to estimate the correlation between hematocrit and circulating RBC volume in infants weighing less than 1300 g. They found that venous hematocrit values correlated highly with the circulating erythrocyte volume ($r = 0.907$; $P < .0001$) (Strauss et al., 2003).

Neonates have a shorter RBC survival than do children and adults. The life span of RBCs from term infants is estimated to be 60 to 80 days with use of the ^{51}Cr method (Pearson and Vertrees, 1961) and 45 to 70 days with use of methods involving ^{59}Fe (Pearson, 1967). Fetal studies using ^{14}C cyanate-labeled RBCs in sheep revealed an average RBC life span of 64 ± 6 days (Brace et al., 2000). Brace et al. found that the mean RBC life span

increased linearly from 35 to 107 days as the fetal age increased from 97 days (midgestation) to 136 days (term). In a similar fashion, neonatal RBCs transfused into adults have a short survival (Pearson, 1967), indicating that factors intrinsic to the newborn RBC are responsible. This conclusion has gained further support by the demonstration that adult RBCs survive normally in newborn recipients (Brace et al., 2000). The life span frequency function is not parametrically distributed, in that most cells are destroyed before the mean survival is reached. Shortened RBC survival corresponds with erythropoietic rates at birth that are three to five times greater than those of normal adults.

At term the placenta and umbilical cord contain 75 to 125 mL of blood (30 to 40 mL/kg), or approximately one-fourth to one-third of the fetal blood volume. Umbilical arteries typically constrict shortly after birth, but the umbilical vein can remain dilated. Early studies suggested that newborns held below the level of the placenta can receive half of the placental blood volume (30 to 50 mL, or

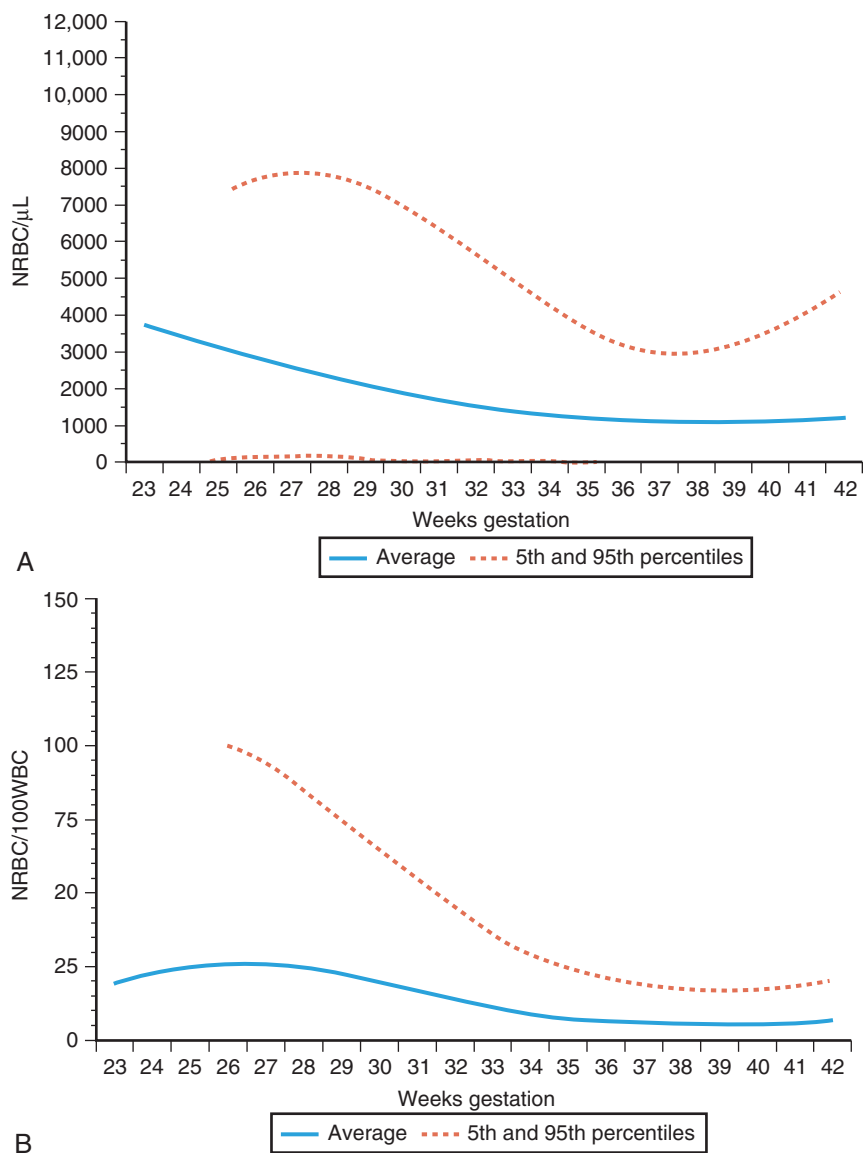

• **Fig. 81.5** Reference intervals for absolute reticulocyte count, immature reticulocyte fraction, and reticulocyte hemoglobin content during the first 90 days after birth. Dashed lines indicate 5th and 95th percentile reference interval. Solid line indicates mean. *HGB*, Hemoglobin; *IRF*, immature reticulocyte fraction; *Retic K*, absolute reticulocyte count; *Retic He*, reticulocyte hemoglobin; *MCV*, mean corpuscular volume. (From Christensen RD, Henry E, Bennett ST, Yaish HM. Reference intervals for reticulocyte parameters of infants during their first 90 days after birth. *J Perinatol*. 2016;36:61–66.)

10 to 15 mL/kg) in 1 minute. Some studies showed that infants held above the placenta can lose 20 to 30 mL of blood back into the placenta per minute (Linderkamp, 1978; Linderkamp et al., 1992), but a more recent study from Argentina refutes this, reporting no effect of position (neonate held at the level of the introitus compared with the mother's abdomen or chest) on the volume of

placental transfusion (Vain et al., 2014). The blood volume of infants with early cord clamping averages 72 mL/kg, whereas the blood volume of infants with cord clamping delayed for 1 minute averages 93 mL/kg.

Linderkamp et al. compared postnatal alterations in blood viscosity, hematocrit, plasma viscosity, RBC aggregation, and

• **Fig. 81.6** Reference intervals for blood concentrations of nucleated red blood cells (NRBCs) on the day of birth according to gestational age: (A) data expressed as number of NRBCs per microliter of blood; (B) data expressed as number of NRBCs per 100 white blood cells. The *lower line* represents the fifth percentile limit, the *upper line* represents the and 95th percentile limit, and the *middle line* represents the median value. WBC, White blood cells. RBC deformability in the first 5 days of postnatal life in term neonates with early (less than 10 seconds) and late (3 minutes) cord clamping (Linderkamp, 1978; Linderkamp et al., 1992). The residual placental blood volume decreased from 52 ± 8 mL/kg neonatal body weight after early cord clamping to 15 ± 4 mL/kg after clamping. The neonatal blood volume was 50% higher in the infants with late cord clamping. Other investigations showed a transfer of about 15 mL/kg body weight by delaying clamping for 60 to 90 seconds (Fig. 81.7) and that this practice reduces intraventricular hemorrhage and late-onset sepsis (Aladangady et al., 2006; Mercer et al., 2006; Strauss et al., 2008). For very low birth weight (VLBW; <1500 g) deliveries, delayed cord clamping or the somewhat more rapid alternative of umbilical cord milking can result in a higher 24-hour hemoglobin concentration and hematocrit and can lower the risk of hypotension, early RBC transfusion, and intraventricular hemorrhage (Rabe et al., 2004, 2009; Carroll and Christensen, 2015). Moreover, drawing all of the needed initial blood studies of VLBW neonates on their admission to the neonatal intensive care unit (NICU) from otherwise discarded blood in the

umbilical cord after placental delivery can result in a higher 24-hour hemoglobin concentration and hematocrit and can lower the risk of initial hypotension (Christensen et al., 2011c, 2014c; Henry et al., 2015).

Neonatal Anemia

Anemia in a neonate can be categorized kinetically as due to either (1) RBC production failure or (2) RBC loss. RBC loss can be the result of bleeding (either occult or obvious blood loss) or hemolysis (Box 81.1). Rarely a neonate has anemia from mixed mechanisms, such as production failure and also bleeding, or disseminated intravascular coagulation (DIC) with both hemolysis and bleeding. However, to facilitate a clear presentation of each element of anemia pathogenesis in neonates, we will discuss the varieties of neonatal anemia using the simple kinetic categorization of production failure, hemorrhage, and hemolysis.

The cause of anemia in a neonate can frequently be suspected on the basis of the history and physical examination findings.

• BOX 81.1 Categorization of Anemia in Neonates

Red Blood Cell Production Failure

Anemia of prematurity
Late anemia of Rh hemolytic disease
Neonatal iron deficiency
Diamond–Blackfan anemia and somewhat related conditions

Hemorrhage

Prenatal
Perinatal
Postnatal

Hemolysis

Immune-mediated diseases: Rh, ABO, Kell, Kidd, Duffy, MNS, maternal autoimmune
Nonimmune-mediated acquired diseases: cytomegalovirus infection, toxoplasmosis, syphilis, sepsis, disseminated intravascular coagulation
Erythrocyte cytoskeletal mutations: hereditary spherocytosis, hereditary elliptocytosis, hereditary pyropoikilocytosis
Erythrocyte enzyme abnormalities: glucose 6-phosphate dehydrogenase deficiency, pyruvate kinase deficiency, unstable hemoglobins, alpha and gamma thalassemia

Particular importance is given to family history (anemia, cholelithiasis, jaundice, splenomegaly), maternal medical history (especially infections), and obstetric history (previous pregnancies, length of gestation, difficulty of delivery). The age at which anemia becomes manifest is also of diagnostic importance. Significant anemia at birth is generally the result of blood loss or alloimmune hemolysis. If anemia first occurs after 24 hours, internal hemorrhages and other causes of hemolysis are likely. Anemia that first appears 1 week or more after birth can be caused by RBC enzyme deficiencies, abnormalities in RBC cytoskeletal proteins, hypoplastic RBC disorders, phlebotomy losses, the physiologic anemia of infancy, or anemia of prematurity.

Newborns with anemia from *chronic* intrauterine blood loss or from intrauterine hemolysis generally appear pale at birth but without other signs of distress. However, *acute* blood loss typically produces hypovolemic shock. Neonates with hemolytic anemia are typically jaundiced, while those with anemia caused by blood loss (fetal–maternal or twin–twin transfusion) are generally not jaundiced. In addition, hemolytic anemia is often accompanied by hepatosplenomegaly, and cases of anemia resulting from congenital infection can have other stigmata of infection such as thrombocytopenia and sometimes cutaneous hemorrhages.

Anemia Caused by Failure of Erythrocyte Production

A hyporegenerative erythropoietic state in a neonate can be transient or long lived. The transient varieties typically relate to hypoproduction of erythropoietin (Epo) or to deficiencies of micronutrients such as iron. The long-lived varieties are typically a result of genetic mutations. We will begin this section on RBC production failure with the transient varieties. These include the common “anemia of prematurity,” the “late” anemia following fetal hemolytic disease, and iron deficiency. Then we will review the long-lived congenital hyporegenerative anemias seen in neonates: Diamond–Blackfan anemia (DBA) and somewhat similar disorders.

Anemia of Prematurity

The abrupt transition from the relatively hypoxic uterus to the relatively oxygen-rich extrauterine environment triggers responses that have profound effects on erythropoiesis. During the first 2 months of life, an infant has both the highest (at birth) and the lowest (physiologic nadir) blood hemoglobin concentrations of its entire (healthy) life. Epo levels at birth are usually well above the normal adult reference range but fall rapidly in the first few days after birth, as oxygen delivery to tissues markedly increases (Kling, 2013). By 24 hours after (healthy) birth, the blood Epo

concentration falls below the normal adult range and remains low throughout the first month. The decrease in Epo level is followed by a decline in erythropoiesis, a fall in the reticulocyte count, and a subsequent lowering of the hemoglobin level/hematocrit.

In healthy term neonates the combination of initial physiologic hemolysis, a shortened cell survival, decreased RBC production, and somatic growth with expansion of the blood volume is responsible for a progressive fall of the blood hemoglobin level to a mean of approximately 11 g/dL at 2 months of age. The lower reference interval for infants of this age is approximately 9 g/dL. This nadir is called *physiologic anemia*, because it is not associated with distress and is not prevented with nutritional supplements. Stabilization of the blood hemoglobin concentration is heralded by an increase in the reticulocyte count at 4 to 8 weeks. Thereafter, the hemoglobin concentration rises to a mean level of 12.5 g/dL, at which it remains throughout infancy and early childhood (Kling, 2013).

In contrast to the situation in healthy term infants, those delivered before about 32 completed weeks of gestation typically develop a transient and unique anemia known as *anemia of prematurity*. During the first week or first 2 weeks after birth, while the neonate is in an intensive care unit, anemia secondary to phlebotomy commonly complicates anemia of prematurity. However, after the period of phlebotomy loss has passed and the neonate becomes basically an NICU “grower,” anemia of prematurity becomes manifest as a normocytic, normochromic, hyporegenerative condition, with serum Epo concentrations significantly below those found in adults with similar degrees of anemia (Brown et al., 1984). In its pure state this anemia is not responsive to the administration of iron, folate, or vitamin E, because it is not due to deficiency of those nutrients. Obviously iron deficiency can complicate anemia of prematurity, and both conditions can coexist.

Some preterm infants who develop anemia of prematurity are asymptomatic, whereas others have clear signs of anemia that are alleviated by erythrocyte transfusion. These signs include tachycardia, rapid tiring with nipple feedings, poor weight gain, increased requirements for supplemental oxygen, episodes of apnea and bradycardia, and elevated serum lactate concentrations.

The reason preterm infants do not significantly increase serum Epo concentration during this anemia is not known. Indeed, it is unclear whether production of Epo does in fact increase, but the serum concentration does not rise. Certainly neonates with anemia of prematurity have erythroid progenitors that are sensitive to recombinant Epo in vitro (Shannon et al., 1987; Rhondeau et al., 1988), and their circulating concentrations of other erythropoietic growth factors appear to be adequate (Ohls et al., 1990).

The molecular and cellular mechanisms responsible for anemia of prematurity remain undefined. Potential explanations include the transition from fetal to adult hemoglobin, shortened erythrocyte survival, and hemodilution associated with a rapidly increasing body mass. It is unknown whether preterm infants rely on Epo produced by the liver (the source of Epo in utero) or that produced by the kidney or a combination of the two.

The “Late” Anemia of Rhesus Hemolytic Disease

Neonates with rhesus (Rh) hemolytic disease typically have an early anemia due to hemolysis and sometimes then develop a late anemia due to erythrocyte production failure. This late anemia is usually severest about 1 month after birth, generally days to weeks after the neonate has been discharged home from the NICU (al-Alaiyan and al Omran, 1999). The incidence of late anemia is highest among the neonates with Rh hemolytic disease who received

intrauterine transfusions. This fact led to the speculation that infusing adult hemoglobin into a fetus in utero leads to a quick downregulation of fetal Epo production and that several weeks are required before this is repaired.

The late anemia is characterized by low serum Epo levels and low reticulocyte counts, but the erythroid progenitors are responsive to Epo in vitro (Koenig et al., 1989; Nicaise et al., 2002; Zuppa et al., 2012). Infants with this variety of anemia are sometimes transfused once, or sometimes two or three times, until the hyporegenerative condition eventually resolves. As an alternative to RBC transfusions, dosing with recombinant Epo or with darbepoetin can be attempted (Ohls et al., 1992; Nicaise et al., 2002; Zuppa et al., 2012). We find this approach far less expensive and more acceptable to parents. However, it is effective only when it is begun before the appearance of signs of anemia. If the hematocrit has fallen below about 20% and signs of anemia are obvious, transfusion is the only effective treatment. Darbepoetin can be given once per week or every other week for two or three doses, after which the problem typically and permanently remits.

Neonatal Iron Deficiency

Adequate iron availability is required for erythropoiesis and is also critical for normal prenatal and postnatal brain development (Rao and Georgieff, 2009). Iron deficiency retards an infant's long-term neurodevelopment, which can be irreversible despite later iron supplementation that corrects the iron deficiency (Fretham et al., 2011; Sani et al., 2011; Callahan et al., 2013; Tran et al., 2013). Anemia is a very *late* sign of iron deficiency. The steps toward iron-deficiency anemia are sometimes labeled as follows (Table 81.1): (1) *iron deficiency*, where biochemical measurements show that the levels of serum and storage iron are low, but measures of erythropoiesis are normal and anemia does not yet exist; (2) *iron-deficient erythropoiesis*, where biochemical measurements of the levels of iron and iron stores are low, and erythropoiesis is reduced but anemia does not yet exist; and (3) *iron-deficiency anemia*, with biochemical iron deficiency, limitations in erythropoiesis, and the presence of microcytic hypochromic anemia. Once iron-deficient erythropoiesis exists, the iron deficiency state has almost certainly begun to cause iron-deficient neurologic impediments, including reduced cognitive performance (Mukhopadhyay et al., 2011).

Iron deficiency in a neonate can be defined by a pattern of findings, including low serum iron concentration, low percent iron saturation, low serum ferritin concentration, low hepcidin concentration, elevated zinc protoporphyrin-to-heme ratio, and elevated soluble transferrin receptor concentration. We see this pattern with some regularity, perhaps 10% or more of cases, in neonates who are small for gestational age (SGA) or in infants of diabetic mothers. It is very rare to find a newborn, at birth, with iron-limited erythropoiesis or with iron-deficiency anemia. However, neonates who are even moderately iron deficient at birth can progress to having iron-limited erythropoiesis and then iron-deficiency anemia and iron-deficient neurocognitive delay.

Current iron supplementation guidelines from the American Academy of Pediatrics (AAP) for term infants include beginning iron supplements for breastfed infants at the age of 4 months and screening for iron deficiency at 12 months (Baker et al., 2010). For preterm infants (<37 weeks) the recommendation is to start iron supplementation by 1 month (2 mg/kg per day) and extend this through 12 months. Specific guidelines for iron dosing and iron-deficiency screening of neonates who are SGA infants of diabetic mothers (IDAs) are not included in that report.

TABLE 81.1 Diagnosis of Iron Deficiency in the Neonatal Period

| Severity | Serum and Storage Iron and Compensations | Reticulocyte Hemoglobin Content, Absolute Reticulocyte Count, Immature Reticulocyte Fraction | MCV, MCH, Hemoglobin Level, and Hematocrit |
|-------------------------------|--|--|---|
| Biochemical iron deficiency | Low serum iron level, percent saturation, ferritin level, hepcidin level High soluble transferrin receptor level, zinc protoporphyrin-to-heme ratio | Within the reference range for gestational and postnatal age | Within the reference range for gestational and postnatal age |
| Iron-deficient erythropoiesis | Same direction as above but the derangements are more pronounced | Below the fifth percentile lower reference interval for gestational and postnatal age | Within the reference range for gestational and postnatal age |
| Iron-deficiency anemia | Same direction as above but the derangements are more pronounced | Below the fifth percentile lower reference interval for gestational and postnatal age | Below the fifth percentile lower reference interval for gestational and postnatal age |

MCH, Mean corpuscular hemoglobin; MCV, mean corpuscular volume.

If 10% or more of SGA or IDM neonates are indeed iron deficient at birth, then over the next few weeks, with no supplemental iron, their iron stores will likely drop further. Perhaps some of these neonates drop their iron stores to the point of iron-limited erythropoiesis. Such a state could be accompanied by significant lack of iron availability to the developing central nervous system, imposing a risk of subsequent neurocognitive deficiencies. However, if iron-deficient neonates could be recognized and safely and effectively treated with iron before iron limitation impairs their erythropoiesis and their brain development, better long-term neurodevelopment might result.

At this point, larger studies are needed to identify neonates at risk of congenital iron deficiency and those likely to develop iron-limited erythropoiesis in the neonatal period. Such studies will provide the data needed to inform the design of definitive randomized trials where neonates with biochemical iron deficiency at birth are randomized to receive iron supplements either according to current guidelines or according to a personalized medicine approach. The primary outcome of such studies would be neurocognitive outcomes.

Diamond–Blackfan Anemia and Somewhat Related Conditions

DBA is a hypoplasia of RBCs characterized by abnormally reduced levels of erythroid precursors in the marrow (Narla et al., 2011; Vlachos et al., 2014). It is a disorder of ribosome biogenesis that causes erythroid hypoplasia, because erythroid progenitors are highly sensitive to apoptotic cell death (Horos and von Lindern, 2012; Ellis, 2014; Nakhoul et al., 2014; Dalle et al., 2016; Khincha and Savage, 2016). Although many cases are sporadic, familial autosomal dominant DBA has been estimated to account for about half of cases. At least 11 different ribosomal protein gene mutations have been identified in DBA patients. Syndromes such as DBA that are associated with congenital hyporegenerative anemia are reviewed in Table 81.2. Anemia in DBA is lifelong but the onset of signs and symptoms is variable. Many individuals with DBA are severely anemic in the newborn period and have pallor at birth. Fetal growth restriction, skeletal abnormalities, or other congenital anomalies are seen in almost one-third of patients. The diagnosis of DBA is suggested by anemia and reticulocytopenia at birth or

appearing in the first 6 months of life. Certain unusual features of the RBCs (macrocytosis, elevated fetal hemoglobin (HbF) level, increased adenosine deaminase activity) can assist one in coming to the diagnosis. Also, tests for many of the DBA gene mutations are available in commercial gene diagnostic laboratories (Narla et al., 2011; Vlachos et al., 2014).

Many infants with DBA achieve durable remissions from anemia when treated with corticosteroids. Those who do not respond require chronic RBC transfusions and are at risk of transfusion iron overload. Transfusion-dependent DBA can be cured by allogeneic bone marrow transplant from HLA-compatible siblings (Lipton, 2006). The incidence of cancer is probably increased in DBA patients, on the basis of cases reported to the Diamond Blackfan Anemia Registry of North America (Lipton and Ellis, 2009). Although a variety of solid tumors, in particular osteogenic sarcoma, have been reported, the most common malignancy has been acute myeloid leukemia.

Neonatal Anemia Caused by Hemorrhage

Underlying causes of hemorrhage that result in fetal or neonatal anemia are noted in Box 81.2 and in this section are divided into prenatal, perinatal, and postnatal hemorrhages.

Prenatal Hemorrhage

Approximately 1 in 400 pregnancies is associated with fetal–maternal hemorrhage (FMH) of 30 mL or more, and 1 in 2000 pregnancies is associated with FMH of 100 mL or more (Kosasa et al., 1993). FMH of small volumes of blood is very common. Perhaps as many as 75% of pregnancies can be shown to have 0.01 to 0.1 mL of fetal blood in the maternal circulation. Fetal blood cells can gain entry into the mother's circulation during abortion. This has been reported in 2% of spontaneous abortions and in 5% of induced abortions (Giacola, 1997).

The Kleihauer–Betke stain of maternal blood evaluates the acid elution of hemoglobin from RBCs (Huissoud et al., 2009). HbF resists acid elution to a greater degree than adult hemoglobin. Therefore maternal cells appear clear (termed *ghost cells*), whereas erythrocytes of fetal origin appear pink. False-positive results occur when mothers have an increase in the level of HbF (i.e., sickle cell

TABLE 81.2**Syndromes Associated With Congenital Hyporegenerative Anemia**

| Syndrome | Phenotypic Features | Genotypic Features |
|---|---|--|
| Adenosine deaminase deficiency | Autoimmune hemolytic anemia, reduced erythrocyte adenosine deaminase activity | AR, 20q13.11 |
| Congenital dyserythropoietic anemias | Type I (rare): megaloblastoid erythroid hyperplasia and nuclear chromatin bridges between nuclei Type II (most common): hereditary erythroblastic multinuclearity with positive acidified serum test result, increased lysis to anti-i Type III: erythroblastic multinuclearity ("gigantoblasts"), macrocytosis | Type I: 15q15.1-q15.3 Type II: 20q11.2 Type III: 15q21 |
| Diamond–Blackfan syndrome | Steroid-responsive hypoplastic anemia, often macrocytic after 5 months of age | AR; sporadic mutations and AD inheritance described; 19q13.2, 8p23.3-p22 |
| Dyskeratosis congenita | Hypoproliferative anemia usually presenting between 5 and 15 years of age | X-linked recessive, locus on Xq28; some cases with AD inheritance |
| Fanconi syndrome | Steroid-responsive hypoplastic anemia, reticulocytopenia, some macrocytic RBCs, shortened RBC life span. Cells are hypersensitive to DNA cross-linking agents | AR, multiple genes: complementation; group A 16q24.3; group B Xp22.3; group C 9q22.3; group D2 3p25.3; group E 6p22-p21; group F 11p15; group G 9p13 |
| Osler hemorrhagic telangiectasia syndrome | Hemorrhagic anemia | AD, 9q34.1 |
| Osteopetrosis | Hypoplastic anemia from marrow compression; extramedullary erythropoiesis | AR, 16p13, 11q13.4-q13.5; AD, 1p21; lethal, reduced levels of osteoclasts |
| Pearson syndrome | Hypoplastic sideroblastic anemia, marrow cell vacuolization | Pleioplasmatic rearrangement of mitochondrial DNA; X-linked or AR |
| Peutz–Jeghers syndrome | Iron-deficiency anemia from chronic blood loss | AD, 19p13.3 |
| ATR-X and ATR-16 syndromes | ATR-X: hypochromic, microcytic anemia; mild form of hemoglobin H disease ATR-16: more significant hemoglobin H disease and anemia are present. | ATR-16, 16p13.3, deletions of alpha globin locus |

AD, Autosomal dominant; *AR*, autosomal recessive; *ATR-16*, chromosome 16–related alpha thalassemia/mental retardation; *ATR-X*, X-linked alpha thalassemia/mental retardation; *RBC*, red blood cell.

• BOX 81.2 Underlying Causes of Hemorrhage in the Fetus and Neonate**Prenatal**

Twin–twin transfusion
Fetal–maternal hemorrhage
Trauma with bleeding into cord, placenta, amniotic fluid

Perinatal

Placenta previa
Placental abruption
Vasa previa
Velamentous insertion of the umbilical cord
Nuchal cord
Trauma or incision of the cord or placenta during cesarean delivery
Rupture of the umbilical cord at delivery

Postnatal

Subgaleal hemorrhage
Cephalohematoma
Organ trauma after birth
Pulmonary hemorrhage
Intracranial hemorrhage
Iatrogenic blood loss

disease, thalassemia, and hereditary persistence of HbF). Diagnosing FMH can be difficult when the mother has blood group O and the infant has blood group A or B because fetal cells are rapidly cleared from the maternal circulation by maternal anti-A or anti-B antibodies and therefore are not detected by the Kleihauer–Betke stain.

Severe FMH can be suspected before delivery by decreased fetal movements and a fetal sinusoidal heart rate pattern (Lopriore et al., 1995). Giacoia (1997) reviewed these variables to determine if they correlated with the severity of FMH. Fetal movements for a period ranging between 24 hours and 7 days were absent in 17 of 134 cases evaluated. In this group, six infants survived, five were stillborn, and five died in the neonatal period. A sinusoidal heart rate pattern was reported in 21 cases and was associated with decreased fetal movement in 40% of the cases. No significant difference was found between the cases with a hemorrhage of less than 200 mL versus those with a hemorrhage of more than 200 mL. Significant FMH has been described following maternal trauma (Huisoud et al., 2009). In a larger study from Intermountain Healthcare, we found an incidence of FMH of 1 case per 9160 live births, with 67% of affected neonates having an initial hemoglobin level below 7 g/dL (Christensen et al., 2012). Outcomes were poorer in those with the lowest initial hemoglobin levels, with death or major morbidities in 100% of those with an initial

value below 5 g/dL and in all who were born before 35 weeks of gestation.

Neonates delivered after a significant FMH can be pale, tachycardic, and tachypneic, but they generally do not have marked respiratory distress or a requirement for supplemental oxygen. Their hemoglobin concentration can be as low as 4 to 6 g/dL, and a significant metabolic acidosis is often present in association with poor perfusion. Other causes of pallor can be ruled out once the infant is stable. Infants with asphyxia or chronic anemia caused by hemolysis can also have pallor. These diagnoses can be distinguished from acute hemorrhage on differences in clinical signs. With chronic blood loss, shock is usually absent. Asphyxiated infants are pale and floppy and may have poor peripheral circulation. The hemoglobin level will be stable but might fall if DIC and internal bleeding occur. [Table 81.3](#) lists potential ways to improve the outcome after FMH.

Twin–twin transfusion is a complication of monochorionic twin gestations, occurring in 5%–30% of such pregnancies ([Domergues et al., 1995](#); [Dennis and Winkler, 1997](#)). It involves placental anastomoses that permit transfer of blood from one twin to the other. The perinatal mortality rate can be 70% or more. About 70% of monozygous twin pregnancies have monochorionic placentas. Although vascular anastomoses are present in almost all such twin pregnancies, not all develop twin–twin transfusion.

Acute twin–twin transfusion generally results in twins of similar size but with hemoglobin concentrations that differ by more than 5 g/dL. In chronic twin–twin transfusion the donor becomes progressively anemic and growth retarded, whereas the recipient becomes polycythemic, macrosomic, and sometimes hypertensive. Both twins can develop hydrops; the donor twin becomes hydropic from profound anemia, and the recipient twin becomes hydropic from congestive heart failure. The donor often has low amniotic fluid volumes, whereas the recipient has increased amniotic fluid volumes because of significant differences in blood volume, renal blood flow, and urine output.

Chronic twin–twin transfusion can be diagnosed by serial prenatal ultrasonography measuring cardiomegaly, discordant amniotic fluid production, and fetal growth discrepancy of more than 20%. An in utero diagnosis is not dependent on differences in hemoglobin concentration; however, percutaneous umbilical blood sampling can determine whether hemoglobin concentrations differ by more than 5 g/dL. After birth the donor twin may require transfusions and can have neutropenia, hydrops from severe anemia,

growth retardation, congestive heart failure, and hypoglycemia. The recipient twin is often the sicker of the two, with problems including hypertrophic cardiomyopathy, congestive heart failure, polycythemia, hyperviscosity, respiratory difficulties, hypocalcemia, and hypoglycemia. Neurologic evaluation and imaging are imperative because the risk of prenatally acquired cerebral lesions is 20%–30% in both twins. The incidence of neurologic morbidity following the intrauterine death of one of the fetuses averages 20%–25%. Morbidities include multiple cerebral infarctions, hypoperfusion syndromes from hypotension, and periventricular leukomalacia. Long-term neurologic follow-up is indicated for all survivors of twin–twin transfusion.

Prenatal treatment for twin–twin transfusion consists of close monitoring and reduction amniocenteses to decrease uterine stretch and prolong the pregnancy. Selective feticide of the hydropic twin has been advocated by some and has resulted in the survival of the healthier twin in some studies ([De Lia et al., 1995](#)). Studies suggest treatment in utero using laser ablation of bridging vessels provides the best outcomes, resulting in survival rates increased up to around 50%, with approximately 70% of the pregnancies having at least one survivor ([Ville et al., 1995](#); [van Hetern et al., 1998](#)). The survival rate without morbidity in the surviving twin is approximately 50%. [Supski et al. \(2002\)](#) performed a metaanalysis of 140 cases to correlate types of treatment with outcome. They found no differences in outcome between amnioreduction, fetoscopy, septostomy, or close observation.

Perinatal Hemorrhage

Perinatal blood loss in the fetus can occur with various obstetric complications, such as placenta previa, placental abruption, incision or tearing of the placenta during cesarean delivery, and cord evulsion. When a fetus undergoes significant blood loss back into the placenta, the term *fetoplacental hemorrhage* is used. Placental anomalies such as a multilobed placenta and placental chorioangiomas can be a source of perinatal bleeding ([Kramer et al., 1997](#)).

Placental abruption occurs in 3 to 6 per 1000 live births. The risk factors for placental abruption include prolonged rupture of membranes, severe fetal growth restriction, chorioamnionitis, hypertension, maternal diabetes, cigarette smoking, and advanced maternal age. The incidence of abruption increases with lower gestational age. Neonatal mortality rates from abruption range from 0.8 to 2.0 per 1000 births, or 15%–20% of the deliveries in which significant abruption occurs ([Rasmussen et al., 1997](#)).

**TABLE
81.3**

Potential Ways to Improve Outcomes After Fetal–Maternal Hemorrhage

| Area of Improvement | Potential Means of Improvement |
|--|--|
| Heightened suspicion of FMH by the obstetric staff | Consider FMH when mother reports lack of fetal movement. Perform a nonstress test or biophysical profile when mother reports lack of fetal movement. Consider FMH in cases with “nonreassuring” fetal heart rate pattern after mother reports lack of fetal movement |
| Increased availability of KB or flow cytometry testing for FMH. Advances in flow cytometry or other means of identifying and quantifying FMH | Availability of best test for FHM to all hospitals with labor and delivery services. More rapid turnaround/reporting of results |
| Rapid and consistent communication that FMH is being considered by the obstetric staff. Rapid communication of positive test results | Communication between clinical laboratory and obstetric staff, labor and delivery staff, pediatric staff, neonatal resuscitation team, neonatology staff, and blood bank staff |

FMH, Fetal–maternal hemorrhage; KB, Kleihauer–Betke.

Women with a history of a cesarean delivery and increased parity are at increased risk of placenta previa (McMahon et al., 1997), a condition where part or all of the placenta overlies the cervical os. Cigarette smoking is associated with a 2.6-fold to 4.4-fold increased risk of placenta previa (Chelmow et al., 1996). Prenatal diagnosis of vasa previa (anomalous vessels overlying the internal os of the cervix) can be made with transvaginal color Doppler ultrasonography and should be suspected in cases of antepartum or intrapartum hemorrhage. Although uncommon (1 in 3000 deliveries), the perinatal death rate is high, ranging from 33% to 100% when this condition is undetected before delivery (Chen and Konchak, 1998).

Neonates delivered after placental abruption or after placenta previa can be anemic, but they can also have signs of hypoxia and ischemia. Most of the blood lost in an abruption or previa is maternal blood, but the neonate can have some degree of anemia as well. Therefore when perinatal blood loss is recognized or suspected, the neonate's hemoglobin level should be measured at birth and again 12 hours or so later. A Kleihauer–Betke stain can be performed on maternal blood to determine if fetal hemorrhage can be documented. Monitoring bleeding mothers with ultrasonography might detect placental abnormalities.

Cord rupture caused by traction on a shortened or abnormal umbilical cord usually occurs on the fetal side. Cord aneurysms, varices, and cysts can all lead to a weakened cord. Cord infections (funisitis) can also weaken the cord and increase the risk of rupture. Infants born precipitously may be at increased risk of hemorrhage due to a ruptured cord.

Cord hematomas occur infrequently (1 per 5000 to 6000 deliveries) and can be a cause of fetal blood loss and perinatal death. Intrauterine death can occur from compression of the umbilical vessels by a cord hematoma. Cord hematomas can result from trauma from percutaneous umbilical blood sampling. Hematomas of the cord can be diagnosed in utero by ultrasonography (Deans and Jauniaux, 1998).

Subamniotic hematomas can occur when chorionic vessels rupture near the cord insertion. Most subamniotic hematomas are the result of traction on a normal or shortened umbilical cord and are not noted until after delivery.

Velamentous insertion of the umbilical cord occurs when the umbilical cord enters the membranes distant from the placenta. This is present in 0.5%–2.0% of pregnancies (Benirschke, 1994). Blood vessels left unprotected by Wharton jelly are more likely to tear. Rupture of anomalous vessels in the absence of traction or trauma can occur even if the cord itself attaches centrally or paracentrally. Fetal mortality remains very high in this condition, often because detection by routine ultrasonography is rare (Eddleman et al., 1992).

Postnatal Hemorrhage

Loss of fetal blood into the placenta can occur during delivery and can be a cause of low-grade neonatal anemia. It is reported to occur when the neonate is held significantly higher than the placenta after birth before the cord is clamped. However, such positioning does not typically result in fetoplacental hemorrhage; in fact even when the neonate is on the mother's abdomen, the unclamped cord typically transfuses fetal blood “uphill” from the placenta to the neonate.

It is possible for neonates to lose blood by fetoplacental transfusion when born with a tight nuchal cord, which allows blood to be pumped through umbilical arteries toward the placenta, while constricting flow back from the placenta to the baby through the

umbilical vein, which is more easily constricted because of its thin wall. However, in actual practice in the Intermountain Healthcare series, most cases of nuchal cord did not result in neonatal anemia (Henry et al., 2013).

Hemorrhage into the subgaleal space can occur before but much more typically after birth. This type of hemorrhage is seen most commonly with difficult deliveries requiring vacuum or forceps assistance (Uchil and Arulkumaran, 2003; Kilani et al., 2006; Christensen et al., 2011a). Subgaleal hemorrhages are potentially life threatening and must be recognized as early as possible to prevent significant morbidity or mortality. In the Intermountain Healthcare series, all cases were diagnosed within a few hours of birth, and the latest were diagnosed by 6 to 7 hours after birth (Christensen et al., 2011a). Subgaleal hemorrhage occurs when veins bridging the subgaleal space are torn, allowing blood to accumulate in the large potential space between the galea aponeurotica and the periosteum of the skull. The subgaleal space extends from the orbital ridge to the base of the skull and can accommodate a volume equivalent to a neonate's entire blood volume (Chadwick et al., 1996; Teng and Sayre, 1997).

Subgaleal hematomas can form or can extend because of risk factors such as coagulopathy or asphyxia, but vacuum extraction itself is a risk factor for their development. The diagnosis should be strongly considered in the presence of a ballotable fluid collection in dependent regions of the infant's head, coupled with signs of hypovolemia. Treatment requires restoration of blood volume and control of bleeding. Death from exsanguination because of subgaleal hemorrhage has been reported. One suggested way to estimate the volume of blood lost is by following head circumference: approximately 40 mL of blood has been lost for every 1 cm increase in head circumference that occurs (Chadwick et al., 1996). The duration of vacuum application has been reported to be a predictor of scalp injury, followed by the duration of the second stage of labor and paramedian cup placement. Of those with reported subgaleal hemorrhages, 80%–90% had some history of vacuum- or instrument-assisted delivery. In the Intermountain Healthcare series, all recognized cases of subgaleal hemorrhage that were severe enough to receive a RBC transfusion occurred after vacuum or forceps deliveries. Limiting the frequency and duration of vacuum assistance in high-risk infants might decrease the incidence of subgaleal hematomas.

Anemia appearing after the first 24 hours of life in a nonjaundiced infant can be a sign of hemorrhage. Hemorrhages can be visible or occult. Breech deliveries can be associated with occult bleeding into the renal, adrenal, hepatic, or splenic organs or into the retroperitoneal space. Delivery of macrosomic infants can result in hemorrhage. Infants with overwhelming sepsis can bleed into soft tissue and organs on the basis of DIC.

In addition to causing anemia, adrenal hemorrhage can result in circulatory collapse because of the loss of adrenal function. The incidence of adrenal hemorrhage is 1.7 per 1000 births (Felic, 1995). Adrenal hemorrhage can also affect surrounding organs. Intestinal obstruction and kidney dysfunction have been reported (Pinto and Guignard, 1995). The diagnosis can be made with ultrasonography, during which calcifications or cystic masses are noted. Adrenal hemorrhage can be distinguished from renal vein thrombosis (RVT) by ultrasonography, in that RVT generally results in a solid mass. Occasionally, both entities coexist.

The liver of a neonate is prone to iatrogenic rupture, resulting in high morbidity and high mortality (Davies, 1997). Neonates with this problem can appear asymptomatic until hemoperitoneum occurs. This problem can occur in term and preterm infants (Emma

et al., 1992) and has been associated with chest compressions during cardiopulmonary resuscitation. Surgical intervention has been reported to save some infants, but the mortality is high. Splenic rupture can result from birth trauma or as a result of distention caused by extramedullary hematopoiesis. Abdominal distention and discoloration, scrotal swelling, and pallor are clinical signs of splenic rupture; these can also be seen with adrenal or hepatic hemorrhage.

More rare causes of hemorrhage in the newborn period include hemangiomas of the gastrointestinal tract (Nagaya et al., 1998), vascular malformations of the skin, and hemorrhage into soft tumors, such as giant sacrococcygeal teratomas. Occult intra-abdominal hemorrhage can occur with fetal ovarian cysts, which are usually benign and resolve spontaneously. One case of fetal anemia was diagnosed by a spontaneous hemorrhage into a fetal ovarian cyst and was managed by intrauterine blood transfusions (Abolmakarem et al., 2001).

Anemia Caused by Hemolysis

Characteristic features of erythrocyte morphology can be used to tentatively classify the cause of neonatal hemolytic disease. Figs. 81.8–81.12 illustrate major categories of neonatal hemolytic disorders that are generally readily identifiable by careful examination of a blood smear (Christensen et al., 2014e).

Erythrocytes of children and adults normally circulate for 100 to 120 days. Erythrocyte survival is shorter in neonates: 70 to 90 days in term infants and 50 to 80 days in premature infants (Pearson, 1967). Hemolysis is defined as a further shortening of erythrocyte survival (Christensen et al., 2015b). A practical, rapid, and non-invasive approximation of the RBC life span can be made by quantification of exhaled CO, with higher values corresponding to a higher hemolytic rate and hence a shorter RBC survival (Christensen et al., 2015c).

The mechanism responsible for shortening the erythrocyte life span can involve macrophage recognition of abnormal RBC membrane properties (extravascular hemolysis, within the reticuloendothelial system) or disruption of circulating erythrocytes (intravascular hemolysis). Both mechanisms can occur simultaneously.

Laboratory tests that support the definition of neonatal hemolysis are shown in Table 81.4. A serum haptoglobin level below the lower detectable limit of the assay and the presence of hemoglobin in the urine in the absence of erythrocytes are both reasonably good indicators of hemolytic disease in neonates. An elevated end-tidal CO concentration is a rapid, practical, and reliable marker of neonatal hemolysis (Christensen and Malleske, 2016).

In older infants and children the usual response to hemolysis is a compensatory increase in erythropoiesis. Because of the increase in erythrocyte production, children with hemolytic disorders sometimes are not anemic or have a hematocrit just at the lower reference interval limit. This occurs when the rate of RBC production increases to exactly match the hemolytic rate. In such cases hyperbilirubinemia and reticulocytosis are seen but anemia is mild. However, neonates are less likely to completely compensate for hemolysis. Perhaps this is because their increased oxygen-carrying capacity, moving from the fetal to the oxygen-rich environment, blunts compensatory erythropoietic activity.

Immune-Mediated Hemolytic Disease of the Neonate

Rhesus

The basis of alloimmune hemolytic anemia is transfer of maternal antibody against fetal RBC antigens inherited from the father and absent in the mother (Huang and Ye, 2010; Christensen and Yaish, 2015, 2016). The severity of the consequent clinical problem ranges from mild neonatal hyperbilirubinemia to severe anemia with hydrops. Since the development of immunoprophylaxis against Rh(D) sensitization, the incidence of alloimmune hemolysis has decreased dramatically, but this remains a global problem in poor

TABLE 81.4**Laboratory Tests That Can Be Performed on Jaundiced Neonates to Assess Them for a Hemolytic Condition**

| Test | Reference Intervals | Problems Applying the Test to Preterm Neonates |
|---|---|---|
| Hemoglobinuria | Trace hemoglobin or greater in urine analysis | RBCs in urine are not uncommon in VLBW neonates. When present they render the urinary hemoglobin test invalid for detection of hemolysis. |
| Low or absent serum haptoglobin | A value that is falling or is below the lower limit of detection | Preterm infants without hemolysis might have very low serum haptoglobin concentrations. |
| DAT (direct Coombs test) | Positive DAT or positive indirect antiglobulin test | Accuracy may be less among VLBW neonates. |
| Elevated absolute reticulocyte count | Above upper limit for GA | Preterm infants can normally have elevated reticulocyte counts, according to GA. |
| Elevated immature reticulocyte fraction | Value above 7% at birth or above 3% after 24 h | Not well validated in VLBW neonates |
| Elevated nucleated RBC count | Upper limit 3000/ μ L at birth. Should be <500/ μ L after 3–4 days | Not well validated in VLBW neonates. The numbers of nucleated RBCs are typically higher in younger GA neonates at birth. |
| Abnormal RBC morphology on stained blood film | Microspherocytes, elliptocytes, bite and blister cells, echinocytes, schistocytes | Anisocytosis and poikilocytosis are frequently encountered in healthy preterm neonates. |
| Heinz body preparation | Heinz bodies support diagnosis of hemolysis due to precipitated (unstable) hemoglobin | Less well studied in preterm infants |
| Elevated ETCOc | First week or first 2 weeks the upper limit is 1.7–2 ppm, thereafter the upper limit is 1 ppm | Reference intervals for VLBW neonates are lacking. Cannot perform test if neonate is intubated or receiving nasal cannula O ₂ . Difficult to get accurate reading if respiratory rate is >60 breaths/min |
| Carboxyhemoglobin by cooximetry | Upper limit is 1.5%–2.0% | Reference intervals for VLBW neonates are lacking, and the measurement is not sensitive. |

DAT, Direct antiglobulin test; ETCOc, end-tidal carbon monoxide concentration; GA, gestational age; ppm, parts per million; RBC, red blood cell; VLBW, very low birth weight (<1500 g).

countries (Zipursky and Bhutani, 2015). In the developed world most cases of alloimmune hemolytic disease of the fetus and newborn are now the result of maternal antibodies to ABO, Kell, Duffy, Kidd, and MNS antigens and other Rh antigens, particularly c and E.

The pathogenesis of Rh hemolytic disease of the fetus and newborn was elucidated by Levine et al. (1941). Several Rh antigens are recognized, each of which is detected by specific antibodies (Huang et al., 2010). Rh blood group antigens are distinct erythrocyte membrane-associated proteins. Two of these have separate isoforms (C and c; E and e), which are detected by specific antibodies (anti-C and anti-c; anti-E and anti-e). The most clinically relevant of the membrane Rh proteins to neonatal hemolytic disease is the D antigen. Rh-positive RBCs are those that possess the D antigen. A lowercase *d* is used to denote the absence of the D antigen, or Rh-negative status; it is not a specific antigen in the same way the c and e antigens are.

The Rh proteins are encoded by two genes on chromosome 1, *RHCE* and *RHD*. *RHCE* encodes the C/c and E/e proteins, and *RHD* encodes the D protein. The Rh-negative phenotype results when the *RHD* gene is deleted or nonfunctional on both chromosomes. In most cases the Rh-negative phenotype is also associated with Rh c and Rh e (i.e., Rh cde). The frequency of Rh negativity differs in different racial groups. It is high in whites (15%), lower in blacks (5%), and very low in Asians. The Rh-positive phenotype may result from homozygosity (DD) or heterozygosity (Dd) for the D antigen. In Rh-positive whites,

approximately 44% are homozygous (DD), and 56% are heterozygous (Dd). Knowledge of differences in *RHD* genotype can be helpful because approximately 25% of fetuses of couples with an Rh(D)-negative mother and an Rh(D)-positive father will be Rh(D) negative and thus not susceptible to Rh hemolytic fetal/neonatal hemolysis.

Rh hemolytic disease is rare during the first pregnancy involving an Rh-positive fetus, but the risk increases with each subsequent pregnancy. This is because small volumes of fetal RBCs enter the maternal circulation throughout gestation, although the major fetomaternal bleeding responsible for sensitization occurs during delivery. Once sensitization has occurred, reexposure to Rh(D) RBCs in subsequent pregnancies leads to an anamnestic response, with an increase in the maternal anti-D titer. Therefore significant hemolysis occurring in the first pregnancy indicates previous maternal exposure to Rh-positive RBCs, a consequence of fetal bleeding associated with a previous spontaneous or therapeutic abortion, ectopic pregnancy, or a variety of different prenatal procedures. On occasion the sensitization is a consequence of an earlier transfusion in which Rh-positive RBCs were administered by mistake or in which some other blood component (e.g., platelets) containing Rh(D) RBCs was transfused.

Fetomaternal transfer of erythrocytes (and thereby sensitization) occurs primarily during delivery. The frequency of Rh immune hemolytic disease is much lower if the mother has blood group O (–) and her fetus has blood group A or B (+). The beneficial effect of ABO incompatibility is due to the maternal anti-A and

anti-B antibodies recognizing the corresponding A and B fetal RBCs, leading to their destruction before sensitization to the Rh antigen(s) can occur. Administration of a single intramuscular dose of Rh immune globulin (300 µg) to unsensitized Rh-negative mothers within 72 hours of their delivering an Rh-positive infant led to the virtual elimination of Rh(D) sensitization (Freda et al., 1975). The few treatment failures seen were attributed to fetomaternal bleeding of more than 30 mL at delivery or bleeding that occurred prenatally. This led to the current standard of practice of administering a full dose of Rh immune globulin to all unsensitized Rh-negative women at 28 weeks of gestation, with an additional dose given at birth if the infant is Rh positive. The dose of Rh immune globulin should be increased when there is greater than normal fetomaternal bleeding.

Fetal bilirubin is removed in utero by transfer across the placenta into the maternal circulation. Thus hyperbilirubinemia is not a problem until after delivery. The major threat to the fetus is severe anemia leading to hydrops and intrauterine death.

Mild hemolytic disease is most common, manifested by a positive direct antiglobulin test (DAT) with minimal hemolysis, little or no anemia (cord blood hemoglobin level greater than 14 g/dL), and minimal hyperbilirubinemia (cord blood bilirubin level less than 4 mg/dL). Aside from early phototherapy, these newborns generally require no therapy unless the postnatal rate of the rise in bilirubin level is greater than expected. Moderate hemolytic disease is found in a smaller fraction of affected infants. This is characterized by hemolysis, moderate anemia (cord blood hemoglobin level less than 14 g/dL), and increased cord blood bilirubin levels (greater than 4 mg/dL). The blood may have numerous nucleated RBCs, decreased numbers of platelets, and occasionally a leukemoid reaction with large numbers of immature granulocytes. Infants with Rh disease also may exhibit marked hepatosplenomegaly, a consequence of extramedullary hematopoiesis and sequestration of antibody-coated RBCs. The risk of development of bilirubin encephalopathy is high if these neonates do not receive intensive phototherapy and sometimes exchange transfusion. Severe hemolytic disease is seen in approximately 25% of affected infants, who are either stillborn or hydropic at birth.

Management of seriously affected fetuses is directed at the prevention of severe anemia and death. To accomplish this it first is necessary to identify those fetuses at risk. An increase in the maternal anti-D titer in a previously sensitized Rh-negative woman is a good serologic measure of a fetus in potential jeopardy. A history of neonatal hemolytic disease resulting from anti-D antibodies suggests that the current fetus also may be at risk. In this regard it may be useful to know the fetal Rh blood type because this identifies those Rh-negative infants who are not at risk. In many cases this can be accomplished by direct Rh typing of fetal RBCs obtained via cordocentesis. Alternatively, molecular biology techniques can be used to determine the Rh genotype in DNA obtained from amniocytes or chorionic villus samples (Daniels et al., 2004). Recently, methods have been developed to perform such analysis of free fetal DNA in maternal blood (Gonenc et al., 2015). When the fetus is found to be Rh negative, no further maternal monitoring or fetal blood studies are necessary.

An increase in the maternal titer of immunoglobulin (Ig) G anti-D indicates maternal sensitization but does not accurately predict the severity of fetal hemolysis. Ultrasonographic signs of hydrops are a relatively late sign of fetal anemia, typically not developing until the hemoglobin content of the fetal blood has fallen to below 7 g/dL for several days. Doppler assessment of peak velocity in the fetal middle cerebral artery (MCA) reflects

the lower viscosity of anemic blood and has become the standard method of screening fetuses for fetal anemia.

Hydrops occurs as early as 20 weeks of gestation. Doppler measurement of the peak velocity in the MCA can begin as early as 18 weeks but more commonly is initiated at approximately 24 weeks, then repeated every 1 to 2 weeks. When the MCA Doppler value exceeds 1.5 multiples of the mean (MoM) (A zone) between 24 and 35 weeks of gestation, cordocentesis is typically performed to measure the hematocrit, fetal blood type, DAT, reticulocyte count, and total bilirubin level. Morbidity from cordocentesis is less than 2%, and cordocentesis should be performed with blood available for intrauterine transfusion if necessary. The donor blood should be type O, Rh(D) negative, cytomegalovirus negative, and less than 72 hours from collection; extended crossmatch is often performed with maternal blood type. Irradiation is mandatory, and many centers also perform leukoreduction. The transfusion is generally administered at approximately 20 mL/kg estimated fetal weight with a target hematocrit of 40%–50%. Neonatal exchange transfusion, amniocentesis, selective early induction of delivery, and intrauterine fetal blood transfusions have all contributed to the declining neonatal death rate from Rh incompatibility.

Administration of intravenous immune globulin (IVIG) to neonates with Rh hemolytic disease was tested as a means of reducing the need for exchange transfusion. The proposed salutary mechanism of action was reduced removal of antibody-coated erythrocytes through Fc receptor blockade. However, randomized trials in the Netherlands (Smits-Womtkems et al., 2011) and Brazil (Santos et al., 2013) showed clearly that IVIG was not effective and can lead to increased hemolysis on the basis of other antibodies introduced in the IVIG preparation (Christensen et al., 2015a).

ABO

Hemolysis resulting from ABO incompatibility is like Rh hemolytic disease in that maternal anti-A or anti-B antibodies cross into the fetal circulation and react with A or B antigens on the surface of the fetal RBC. The ABO locus is on chromosome 9 at 9q34.1-q34.2. In mothers with type A or type B blood, naturally occurring anti-B and anti-A isoantibodies are typically IgM antibodies and consequently do not cross the placenta to affect fetal RBCs. In contrast, the anti-A and anti-B alloantibodies present in mothers with type O blood typically also include IgG antibodies that can cross the placenta and affect the fetal erythrocytes. For this reason, ABO hemolytic disease of the fetus and newborn is largely limited to type O mothers carrying type A or type B fetuses. The presence of IgG anti-A or anti-B antibodies in type O mothers also explains why hemolysis caused by ABO incompatibility frequently occurs during the first pregnancy without prior sensitization. ABO incompatibility is present in approximately 12% of pregnancies, although evidence of fetal RBC sensitization by positive direct antiglobulin testing of fetal RBCs is found in only 3% of births, and less than 1% of births are associated with significant hemolysis. A and B antigens are present in many tissues besides RBCs, and therefore only a fraction of anti-A or anti-B antibody crossing the placenta actually binds to fetal erythrocytes, the remainder being absorbed by other fetal tissues.

In suspected cases of ABO incompatibility, it is essential to exclude other antibodies and other nonimmune causes of hemolysis such as glucose 6-phosphate dehydrogenase (G6PD) deficiency or hereditary spherocytosis. In most cases, pallor and jaundice are minimal. Hepatosplenomegaly is uncommon. Laboratory features include evidence of minimal to moderate hyperbilirubinemia and, occasionally, some degree of anemia. The DAT is sometimes negative,

although the indirect antiglobulin test (neonatal serum plus adult group A or group B RBCs) result is more commonly positive. This paradox is related to the fact that fetal RBCs, compared with adult erythrocytes, have less type-specific antigen on their surface (Voak and Williams, 1971). The peripheral blood smear is characterized by marked spherocytosis that is similar to that seen in hereditary spherocytosis.

Hemolysis in ABO incompatibility is usually mild, presenting with some degree of hyperbilirubinemia but not with anemia and not with hydrops. However, ABO hemolytic disease has been described as the most often found explanation for extreme hyperbilirubinemia and kernicterus (Johnson et al., 2009). Whereas most cases, even severely affected cases, are treated effectively with phototherapy, occasionally exchange transfusion with group O Rh-compatible RBCs is used. Additional follow-up at 2 to 3 weeks of age to check for anemia in these infants is essential.

Kell

Antibody to Kel 1 (K) is a significant cause of hemolytic disease of the newborn (Denomme, 2015; Karagol et al., 2012). This system is the third most common cause of hemolytic disease of the fetus and newborn, after ABO and Rh disease. The *KEL* gene is located on chromosome 7 (7q33). The Kell system was named for the woman in whom this antibody was first detected. The Kell antigen is the first RBC-specific blood group antigen to be expressed during the burst-forming unit–erythroid stage of RBC development. As a consequence, when maternal antibody is expressed to this antigen, it can target early erythroid progenitors and create what appears to be a hypoproliferative anemia. It appears hypoproliferative because the reticulocyte count is commonly low or normal, and hyperbilirubinemia is not as severe as otherwise expected. Thus a fetus/neonate with anti-K hemolytic disease will typically have severe anemia without reticulocytosis or hyperbilirubinemia. This situation can initially be confused with fetal blood loss, such as fetomaternal transfusion. Antibody to Kel 1 is found in about 1 per 1000 pregnant women. Many of these women developed this antibody after blood transfusion.

Kidd

The Kidd antigen is a urea transporter on the surface of RBCs (Ferrando et al., 2008; Thakral et al., 2010). This antigen transports urea out of and into erythrocytes, maintaining the RBC shape and osmotic stability. The three common variants in this transporter are termed *Jka*, *Jkb*, and *Jk3*. *Jka* and *Jkb* differ from each other only in one base pair. The gene encoding the Kidd glycoproteins is located on chromosome 18 (18q11-q12). The Kidd antigen was named after Mrs. Kidd, who was found to have antibodies against a then unknown RBC antigen that her cells lacked but that were expressed on the RBCs of her neonate. Maternal anti-Kidd antibody can produce hemolytic disease of the fetus and newborn, but it is not typically severe enough to cause hydrops or to require intra-uterine transfusion or exchange transfusion. However, it can be a cause of hazardous hyperbilirubinemia.

Duffy

The RBC surface antigens that constitute the Duffy blood group are glycoproteins that are the attachment site for the malarial pathogen *Plasmodium vivax*. The Duffy antigen has two main forms (Fya and Fyb), which differ in only a single amino acid (Hughes et al., 2007; Meny, 2010). Other rare Duffy variants are termed *Fy3*, *Fy4*, *Fy5*, and *Fy6* (but only *Fy3* appears to be of clinical significance). The Duffy blood group was named for a

patient with hemophilia who had received many blood transfusions and developed anti-RBC antibodies. The Duffy locus is on chromosome 1 at position q22-q23. The null variant of the Duffy antigen is termed *Fy(a-b-)* and is the result of a single base pair change in the promotor at the site of binding for GATA-1, a hematopoietic transcription factor. This null variant does not express either Fya or Fyb on its RBCs and is found in more than 95% of West Africans, where it likely is an adaptation to the environmental pressure of malaria, as it seems to reduce the binding of *P. vivax* to erythrocytes. Specifically, RBCs that lack the Duffy antigens are relatively resistant to invasion by *P. vivax*. Maternal antibody to the Duffy antigens has been reported as a rare cause of hemolytic disease of the fetus and neonate. It is typically a mild condition.

MNS

After the ABO blood groups were discovered by Landsteiner in 1900, experiments were performed to identify other blood groups (Reid, 2009). The MNS system was the second blood group identified. The MN and S antigens are glycoproteins on the RBC surface. M and N are glycoprotein A, and S and s are glycoprotein B. Antigens S and s differ by only one amino acid. During erythrocyte development, glycoprotein A is detected shortly after the Kell antigen. The genes encoding the MNS antigens are located on chromosome 4 (4q28.2-q13.1). Rare MNS antigens have resulted from mutations in the glycoprotein A and glycoprotein B genes. Antibodies to the MNS antigens account for only 5% or less of cases of hemolytic disease of the fetus and newborn. Anti-M and anti-N are not considered to be a cause of transfusion reactions. Most neonates affected with anti-MNS hemolytic disease have hyperbilirubinemia that is manageable with phototherapy. Cases where exchange transfusions were used have been reported.

Maternal Disease

Maternal autoimmune hemolytic anemia or lupus erythematosus during pregnancy is sometimes associated with passive transfer of IgG antibody to RBC antigens. The diagnosis is suggested by the presence of neonatal hemolytic disease, a positive DAT, absence of Rh or ABO incompatibility, and antiglobulin-positive hemolysis in the mother (Lewin and Bussell, 2015). Treatment with prednisone in the mother may reduce both maternal hemolysis and the risk of neonatal morbidity. As in other cases of neonatal hemolysis, treatment is focused on prevention of severe hyperbilirubinemia.

Nonimmune-Mediated, Acquired Hemolytic Disease of the Neonate

Cytomegalic inclusion disease, toxoplasmosis, syphilis, bacterial sepsis, and DIC can all be associated with hemolytic anemia. In most of these conditions, some degree of thrombocytopenia also exists, and often hepatosplenomegaly is present. In cases of bacterial sepsis, both the direct and the indirect bilirubin levels may be elevated. The mechanism of hemolysis associated with infection can involve intravascular destruction of RBCs when they are tethered on fibrin strands. Broken erythrocytes can create erythrocyte fragments or deformed cells called *schistocytes*.

Hereditary Hemolytic Anemias Caused by Red Blood Cell Cytoskeletal Mutations

Hereditary Spherocytosis

Hereditary spherocytosis (HS) is a heterogeneous disorder in which abnormalities of RBC structural proteins lead to loss of erythrocyte

membrane surface area, resulting in spherical, hyperdense, poorly deformable RBCs (see Fig. 81.8) with a shortened life span (Perrotta et al., 2008; Sangerman et al., 2008; Christensen and Henry, 2010; Sheffield and Christensen, 2011; Gallagher, 2013; Christensen et al., 2015c). It occurs worldwide and affects individuals from all racial and ethnic groups. Individual pediatricians encounter HS uncommonly, but hospitals and healthcare systems with large delivery services deal with this condition regularly, particularly in white neonates of northern European ancestry, in whom the condition can be as frequent as 1 in 1000 to 2000 births. Early

suspicion and diagnosis of HS allow appropriate management, including provision of anticipatory guidance to parents, which can reduce the risk of adverse outcomes.

The loss of membrane surface area in HS erythrocytes is due to defects in various erythrocyte membrane proteins: ankyrin 1, band 3, β -spectrin, α -spectrin, and protein 4.2 (Table 81.5 and Fig. 81.13). Numerous mutations in the genes encoding these membrane proteins have been described. Destruction of poorly deformable HS erythrocytes in the spleen is the primary cause of hemolysis in patients with HS.

TABLE 81.5 Erythrocyte Membrane Proteins Involved in Hereditary Spherocytosis

| Protein | Gene | Chromosomal Location | Percentage of Hereditary Spherocytosis Cases | Typical Severity | Inheritance |
|--------------------|---------------|----------------------|--|------------------|---------------------|
| Ankyrin 1 | <i>ANK1</i> | 8p11.2 | 40–50 | Mild to moderate | Autosomal dominant |
| Band 3 | <i>SLC4A1</i> | 17q21 | 20–35 | Mild to moderate | Autosomal dominant |
| β -Spectrin | <i>SPTB</i> | 14q23-24.1 | 15–30 | Mild to moderate | Autosomal dominant |
| α -Spectrin | <i>SPTA1</i> | 1q22-23 | <5 | Severe | Autosomal recessive |
| Protein 4.2 | <i>EPB42</i> | 15q15-21 | <5 | Mild to moderate | Autosomal recessive |

• **Fig. 81.13** The red cell membrane, showing the subunits described to have genetic defects as the basis for congenital abnormalities in erythrocyte shape and predisposing to neonatal hemolytic jaundice. (From Gallagher PG. Disorders of erythrocyte metabolism and shape. In: Christensen RD, ed. *Hematologic Problems of the Neonate*. Philadelphia, PA: WB Saunders; 2000:224)

The clinical spectrum of HS during the perinatal period ranges from severe fetal anemia with hydrops fetalis to the asymptomatic neonate. This wide range is due, in part, to the various genes and specific mutations involved and also the presence or absence of coinherited conditions. For instance, HS coinherited with mutations or polymorphisms of genes involved in bilirubin uptake into hepatocytes (*SLC01B1*) or intrahepatic bilirubin conjugation (*UGT1A1*) can increase the risk of hazardous hyperbilirubinemia and kernicterus (Iolascon et al., 1998; Berardi et al., 2006; Korkmaz et al., 2011).

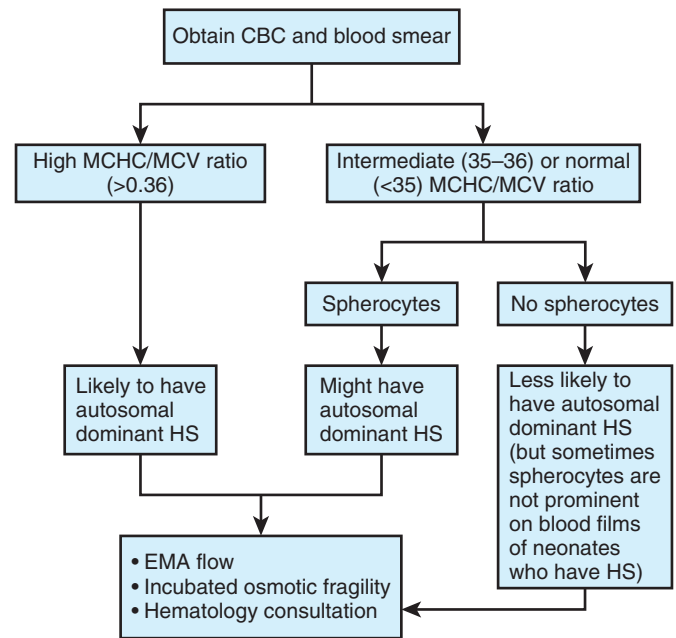

Jaundice is the most common presenting feature of HS in neonates (Delhommeau et al., 2000). In addition, the typically sluggish erythropoietic response of neonates often renders the reticulocyte count low relative to the degree of anemia, spherocytes are less often observed on the blood smear of neonates, and other markers of hemolysis seen in older patients, such as low haptoglobin levels (Chavez-Bueno et al., 2011), may be poor indicators of hemolysis in the neonate.

About 65% of neonates with HS have a parent with HS. When a parent has HS, it is very important that this information be placed prominently in the prenatal record and communicated verbally, before birth, to the physicians and the hospital staff who will be providing neonatal care. All parents with HS should be encouraged to communicate this information to their baby's physician before delivery. Failure to communicate this information sometimes occurs when the affected parent has been asymptomatic since splenectomy as a child and has all but forgotten about the condition and fails to consider that it might be problematic for the newborn. It can be helpful to specifically inquire of parents of anemic and/or jaundiced neonates about a family history of anemia, jaundice, splenectomy, or early gallstones.

One way to suspect HS in a jaundiced neonate is to obtain a complete blood count for interpretation of the RBC indices—in particular the MCHC and the MCV—and to examine the peripheral blood smear for the presence of spherocytes and polychromasia (Christensen et al., 2014e). Typically, a neonate with HS will have an elevated MCHC. Another way to estimate whether or not a neonate has HS takes advantage of the fact that in most neonates with HS the MCV is low. On the basis of this, the “neonatal HS ratio” can be calculated by division of the MCHC by the MCV. With use of this ratio, little overlap is seen between normal neonates and those later proven to have HS. In the Intermountain Healthcare database, a neonatal HS ratio greater than 0.36 indicates that HS is present with 97% sensitivity, more than 99% specificity, and more than 99% negative predictive value (Yaish et al., 2013).

Fig. 81.14 reviews our recommendations for how to evaluate a neonate for HS when a parent is known to have HS. Since the common forms of HS are inherited in an autosomal dominant manner, each child born to a parent with HS has a 50% chance of inheriting the disorder. The key element in the algorithm is to treat the neonate as if he or she has HS until proven otherwise. This includes, in addition to obtaining erythrocyte indices, peripheral smear examination, and reticulocyte count, adhering to the AAP guidelines for bilirubin monitoring in the birth hospital, aggressive phototherapy when indicated, and a follow-up bilirubin check no later than 24 hours after the hospital discharge.

Fig. 81.15 reviews our recommendations for evaluating a jaundiced neonate for HS when neither parent has HS. There is no need to wait until the neonate is several months old, or until significant anemia develops, to begin the evaluation. If these algorithms are followed, the diagnosis can often be made during the birth hospitalization.

• **Fig. 81.14** Evaluation of a neonate, during the birth hospitalization, whose parent has hereditary spherocytosis. *CBC*, Complete blood count; *EMA*, eosin 5-maleimide; *HS*, hereditary spherocytosis; *MCHC*, mean corpuscular hemoglobin concentration; *MCV*, mean corpuscular volume.

The presence of spherocytes on a peripheral blood smear is helpful when one is considering the diagnosis of HS (see Fig. 81.8; Christensen et al., 2014e), but up to one-third of neonates with HS do not have spherocytes identified prominently on their blood smear. Some neonates with band 3 deficiency have “pincered” RBCs (Jarolim et al., 1996). A subset of neonates with DAT-negative ABO incompatibility severe enough to produce spherocytes on a peripheral smear has been described. In most cases the differentiation from HS is clear (family history, maternal/infant blood group analysis, etc.), but additional testing such as elution of anti-A or anti-B from neonatal erythrocytes or detection of free anti-A or anti-B IgG antibody in neonatal serum (indirect antiglobulin test) can clarify the diagnosis.

When the diagnosis of HS is in doubt, eosin 5-maleimide (EMA) binding or osmotic fragility testing can be helpful (King and Zanella, 2013; Christensen et al., 2014a). EMA binding is a flow cytometry–based test that measures the relative amount of fluorescently labeled EMA dye bound to band 3 and Rh-related proteins in the erythrocyte membranes. In HS, the reduction in the levels of band 3 and other membrane proteins leads to decreased fluorescence intensity. In the Primary Children’s Hospital Hematology Clinic, EMA flow has outperformed other diagnostic tests for HS in newborns.

Table 81.6 lists laboratory evaluations we judge as helpful in diagnosing HS in a neonate. Sequencing of the relevant genes can be undertaken as a confirmatory test, available in a few reference laboratories, when desired (Christensen et al., 2013). We reserve genetic sequencing for cases with no family history and a severe HS phenotype so as to make a clear diagnosis, allowing appropriate therapy, and to provide parents and family members with genetic information for counseling regarding recurrence risk.

Phototherapy should reduce the bilirubin level of jaundiced neonates with HS, and it is the mainstay of treatment in the first

• **Fig. 81.15** Evaluation of a neonate with problematic jaundice where the cause is unclear. Not all neonates who receive phototherapy for 2 days or more have hemolytic jaundice. However, if hemolytic jaundice is suspected, this algorithm for stepwise evaluation of the cause might be useful. *CBC*, Complete blood count; *DAT*, direct antiglobulin test; *EMA*, eosin 5-maleimide; *G6PD*, glucose 6-phosphate dehydrogenase; *HS*, hereditary spherocytosis; *MCHC*, mean corpuscular hemoglobin concentration; *MCV*, mean corpuscular volume; *RBC*, red blood cell.

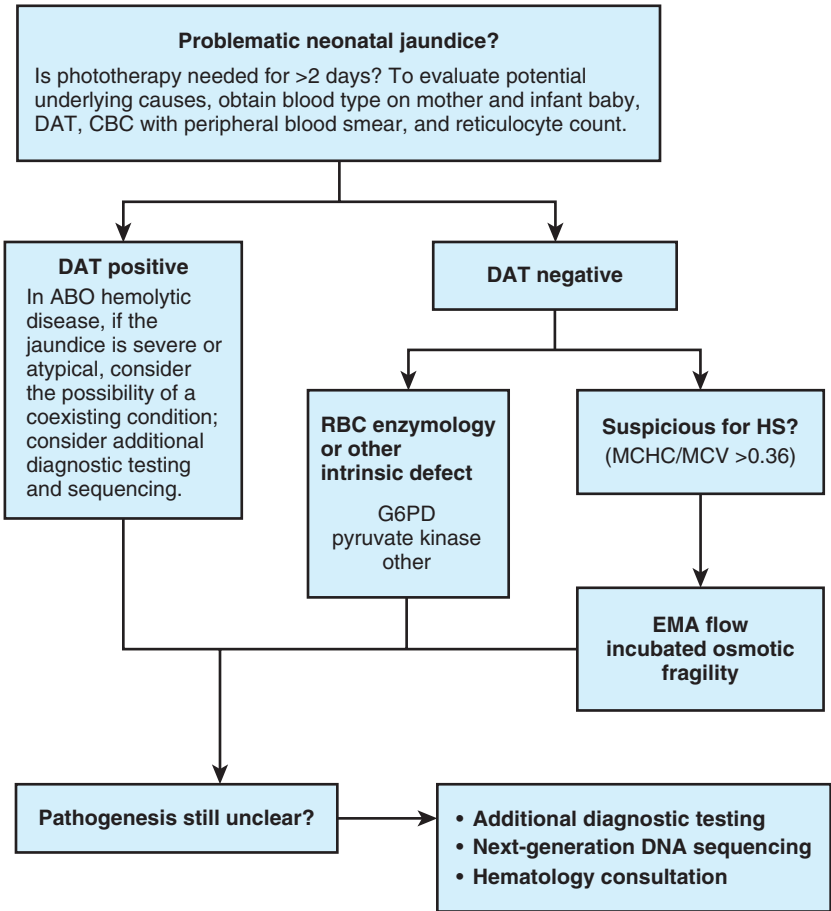

TABLE 81.6 Laboratory Evaluation for Hereditary Spherocytosis in a Jaundiced Neonate

| HS Ratio (MCHC/MCV) | EMA Flow ^a | Incubated Osmotic Fragility | DNA Sequencing ^b |
|---|--|--|---|
| Neonates with HS will generally have a high MCHC and a low MCV, giving an elevated ratio (>0.36). | EMA dye binds stoichiometrically to band 3 and Rh-related membrane proteins. Decreased fluorescence intensity of EMA-tagged erythrocytes caused by loss of membrane proteins is seen in HS. Decreased EMA binding is also seen in other disorders, such as hereditary pyropoikilocytosis and congenital dyserythropoietic anemia II. | HS erythrocytes are more susceptible to osmotic lysis than normal erythrocytes because of decreased membrane surface area. Incubation overnight stresses the already fragile HS erythrocyte, accentuating the defect. Spherocytes from any cause, including ABO incompatibility, will yield a positive osmotic fragility test. | Not needed to diagnose most cases of HS. However, it can establish the diagnosis in difficult cases. Consider sequencing of relevant genes when family history is negative and severe DAT-negative hemolysis is idiopathic. |

few days after birth (Maisels and McDonagh, 2008; Dennerly et al., 2001; Johnson and Bhurtani, 2011). When a bilirubin level is found to be in the high or high-intermediate risk zone (>75th percentile reference interval), phototherapy should be provided immediately. An exchange transfusion followed by intensive phototherapy should follow AAP guidelines (Maisels et al., 2009).

When signs of anemia appear, packed erythrocyte transfusions are helpful. Longitudinal studies indicate that transfusion requirements abate in most patients by 1 year of age. The few patients who remain transfusion dependent, typically those with severe anemia in utero or immediately after birth, have severe HS. Erythropoiesis-stimulating agents (recombinant Epo [rEpo] or darbepoetin) have sometimes been used as an alternative or adjunct

to transfusion (Tchernia et al., 2000; Neuman-Laniec et al., 2002; Schiff et al., 2003). The rationale for rEpo treatment relates to the relative hypoplastic phase of erythropoiesis during the first few weeks to months after birth. This phase might be related to the abrupt fall after birth from the highly stimulated erythropoiesis during fetal life, the switch of Epo production from the liver to the kidney, the switch from fetal to adult hemoglobin, or a lower serum level of Epo in infants compared with older children. Patients with moderate or severe HS should receive folate supplementation to prevent complications of folic acid deficiency. Splenectomy is rarely undertaken in the first year of life. Because hemolysis abates in most patients, careful symptomatic management is prudent, with transfusion therapy as indicated.

Hereditary Elliptocytosis

Hereditary elliptocytosis is an autosomal dominant clinically heterogeneous group of disorders caused by mutations of the RBC membrane cytoskeletal proteins, usually α -spectrin or protein 4.1 (Da Costa et al., 2013; Soderquist and Bagg, 2013; Swierczek et al., 2013; King et al., 2015). These weaken skeletal protein interactions and increase erythrocyte mechanical fragility. Heterozygotes usually exhibit elliptocytes on the blood smear, but in most instances hemolysis is well compensated for by reticulocytosis. Homozygotes or compound heterozygotes may have sufficient weakening of the cytoskeleton to cause significant hemolysis accompanied by striking abnormalities in RBC morphology.

Most neonates with autosomal dominant hereditary elliptocytosis have minimal problems with hemolysis, and they go on to have asymptomatic elliptocytosis. In some neonates, RBC fragility is abnormal, and jaundice and anemia are problematic, but as HbF levels decline postnatally, fragility lessens, hemolysis disappears, and RBC morphology undergoes a transition from poikilocytosis to elliptocytosis.

Hereditary Pyropoikilocytosis

Hereditary pyropoikilocytosis (HPP) occurs in an autosomal recessive fashion, generally when one parent has hereditary elliptocytosis with a mutation in the gene encoding α -spectrin (*SPTA1*) on chromosome 1 at 1q23.1 and the other parent is hematologically normal but is a “silent carrier” of a relevant mutation in the same gene (Swierczek et al., 2013). The molecular basis is typically compound heterozygosity involving a missense mutation causing a severe spectrin dimer self-association defect inherited from the parent with hereditary elliptocytosis, in *trans* with an hypomorphic mutation of *SPTA1*^{LELY}, known as α -spectrin *Lelly*. *SPTA1*^{LELY} is typically asymptomatic and is a relatively high-frequency polymorphism. However when coinherited with other mutations in *SPTA1*, this can underlie an α -spectrin deficiency giving rise to a phenotype much severer than hereditary elliptocytosis. Clinical findings of neonates with HPP include significant hyperbilirubinemia, hemolytic anemia that can require periodic RBC transfusions (Ramos et al., 2007; Christensen et al., 2014d), and a propensity to develop parvovirus-induced aplastic crisis. Fig. 81.16 shows blood smears from an asymptomatic father who had a few elliptocytes, a hematocrit of 40%, and a reticulocyte count of 1%, a mother who had hereditary elliptocytosis, a hematocrit of 32%, and a reticulocyte count of 7.4%, and the baby, who had HPP with a hematocrit of 22% and a reticulocyte count of 9%.

Hereditary Hemolytic Anemias Caused by Red Blood Cell Enzyme Abnormalities

Hyperbilirubinemia, anemia, and hydrops fetalis can result from inherited erythrocyte enzymopathies. The two most commonly encountered such disorders are G6PD deficiency and pyruvate kinase (PK) deficiency.

• **Fig. 81.16** Photomicrographs of blood from (A) the father, (B) the mother, and (C) the neonate. The father had a few elliptocytes, the mother had many elliptocytes, and the neonate had a wide variety of abnormal shapes, including microspherocytes, schistocytes, helmet cells, and elliptocytes.

Glucose 6-Phosphate Dehydrogenase Deficiency

G6PD deficiency is an X-linked disorder affecting millions of people throughout the world, particularly in Mediterranean countries, the Middle East, Africa, and Asia. G6PD deficiency is thought to have become common because it provides a measure of protection against malaria. In most G6PD-deficient people, hemolysis and anemia are present only episodically, precipitated by infection, exposure to medications that are potent oxidants, or exposure to other agents, such as fava beans, naphthalene, or certain petrochemical-derived substances. Rarely, hemolytic anemia is chronic rather than episodic. The clinical heterogeneity of G6PD deficiency is due to the different mutations, usually single amino acid substitutions, which lead to altered enzyme function (Luzzatto et al., 2016).

Normal RBCs contain abundant amounts of reduced glutathione (GSH), a sulfhydryl-containing tripeptide that serves as an intracellular antioxidant, neutralizing oxidant drug metabolites and activated oxygen species. G6PD-deficient RBCs have a limited capacity to regenerate GSH from oxidized glutathione. In the absence of GSH, hemoglobin is vulnerable to oxidant injury, and denatured globin precipitates as Heinz bodies that bind to the cell membrane, alter its structure and function, and lead to hemolysis (see Fig. 81.10).

The variant G6PD A⁻ is responsible for nearly all of the G6PD deficiency seen in Africans (present in approximately 10% of African Americans). It is due to Val68Met and Asn126Asp, which affect the stability of the enzyme, causing an accelerated decline in activity during the life span of the RBC. Only in the oldest RBCs does enzyme activity decline to low enough levels to create vulnerability to oxidant hemolysis. For this reason hemolysis is typically mild and self-limited. Favism is not seen in African Americans with G6PD A⁻. In contrast, in Asians and individuals of Mediterranean or Middle Eastern descent, G6PD deficiency decreases the enzyme activity in young as well as old RBCs, and thus hemolysis is usually more severe.

The gene for G6PD is located on the X chromosome. All of the RBCs of G6PD-deficient males are affected by the enzyme deficiency, whereas a variable fraction of RBCs of G6PD-deficient females are enzyme deficient, depending on the degree of lyonization. Thus hemolysis caused by G6PD deficiency occurs mainly in males.

The diagnosis of G6PD deficiency in a neonate is suggested by DAT-negative hemolytic anemia, where the RBCs sometimes have distinctive features (Christensen et al., 2014e), including bite and blister types caused by splenic removal of Heinz bodies (see Fig. 81.10). Measurement of enzyme activity may not reveal the deficiency in African Americans immediately after a hemolytic episode, because the population of enzyme-deficient cells has been eliminated. Repeat of the assay at a later date is often necessary. Identification of specific G6PD mutations by DNA analysis is available from reference hematology laboratories.

In the neonatal period the major manifestation of G6PD deficiency is hyperbilirubinemia. Jaundice is not typically present at birth, with clinical onset between day 2 and day 3 (Kaplan et al., 2016). Most infants with hyperbilirubinemia caused by G6PD deficiency are of Mediterranean, Middle Eastern, or Asian descent.

The severity of jaundice differs widely. Data from the USA Kernicterus Registry from 1992 to 2004 indicate that more than 30% of kernicterus cases are associated with G6PD deficiency. These observations have raised the question of whether testing for G6PD deficiency should be included in all newborn screening programs (Kaplan et al., 2016).

Therapy for neonatal hemolysis and hyperbilirubinemia resulting from G6PD deficiency includes (1) phototherapy or exchange transfusion to prevent kernicterus, (2) RBC transfusion for symptomatic anemia, (3) removal of potential oxidants that may be contributing to hemolysis, and (4) treatment of infections using agents that do not themselves initiate hemolysis.

Pyruvate Kinase Deficiency

PK deficiency is an autosomal recessive disorder occurring in all ethnic groups (Grace et al., 2015). It is the most common defect of the Embden–Meyerhof pathway, but it is rare in comparison with G6PD deficiency. The overall incidence in the United States is perhaps one case in 20,000 births, but the frequency is much higher in certain groups where consanguinity is common (Christensen et al., 2011d). PK is one of the two RBC enzymes that generate adenosine triphosphate. Nonerythroid cells have other ways to generate adenosine triphosphate, and therefore clinical abnormalities in PK deficiency are limited to RBCs. More than 180 different mutations have been found in *PKLR*, the gene that encodes PK in erythrocytes (Zanella et al., 2007). The variations in the severity of jaundice and anemia among individuals with PK deficiency reflect this genetic diversity.

PK deficiency should be considered in the differential diagnosis of a neonate with unexplained Coombs negative, nonspherocytic hemolytic jaundice when neither parent has a history of jaundice and anemia, particularly when the RBC morphology of the neonate is consistent with PK deficiency (see Fig. 81.11).

Neonates with PK deficiency have jaundice and go on to have anemia. RBC transfusions for anemia are occasionally required but not typically during the first 2 weeks. Splenectomy can reduce the rate of hemolysis but should be avoided in infancy and early childhood because of the high risk of infection.

Neonatal Hemolysis Associated With Unstable Hemoglobins

Certain mutations in the gamma globin gene *HBG1* on chromosome 11 and on the alpha globin gene *HBA1* on chromosome 16 can render the hemoglobin molecule unstable, resulting in insoluble hemoglobin precipitates in erythrocytes (Glader, 2013). These precipitates are recognized by a supra vital stain and are termed *Heinz bodies*. When Heinz bodies are removed from erythrocytes in the spleen, bite cells, blister cells, and other schistocytic forms are seen, and hemolytic jaundice and anemia occur. Hemoglobin Hasharon is due to an Asp47His mutation in the alpha globin gene (*HBA1*) and results in unstable binding with the gamma chain in the production of HbF. After the gamma to beta switch, this variety of hemolytic anemia ceases. In a somewhat similar fashion, a Trp130Gly mutation in the gamma globin gene (*HBG1*) results in hemoglobin F Poole, which renders HbF unstable. As with hemoglobin Hasharon, once gamma chain synthesis has been replaced by beta chain synthesis, the hemolytic anemia ceases. In the neonatal period these conditions look very similar to G6PD deficiency, with similar blood films and clinical manifestations, but with normal G6PD enzyme levels; however, hemolysis from hemoglobin F Poole and hemoglobin Hasharon remits completely in the first month or so (Glader, 2013).

Neonatal Hemolysis Associated With Alpha or Gamma Thalassemia

Beyond infancy the predominant hemoglobin tetramer is hemoglobin A, which is composed of two alpha globin chains and two beta globin chains. To appreciate the hemoglobinopathies that can

occur in a neonate, it is helpful to understand the normal developmental changes that occur in globin synthesis during fetal and neonatal life (Glader, 2013). Embryonic hemoglobins are composed of zeta and epsilon chains. The transition from zeta to alpha globin chains is complete by the end of the first trimester. Epsilon chains disappear more slowly and are replaced first by gamma chains to form HbF (which is $\alpha_2\gamma_2$) and next by beta chains to form hemoglobin A. The various possible combinations of these different globin chains form a number of different hemoglobin tetramers that are characteristically found in embryonic, fetal, and postnatal life.

HbF is the major hemoglobin found in fetuses after the first trimester. Its replacement by adult hemoglobin A begins before birth, such that 60%–90% of the hemoglobin in the normal term infant is hemoglobin F. After birth, gamma chain synthesis declines rapidly as beta chain synthesis increases, so most newly formed hemoglobin is hemoglobin A. As RBCs made before birth are replaced postnatally, the percentage of hemoglobin F declines rapidly, reaching a level of approximately 5% by 6 months of age. Disorders of beta globin, such as sickle cell disease and beta thalassemia major, are not clinically apparent until several months of age, when the switch from hemoglobin F to hemoglobin A synthesis reveals the defect. In contrast, gamma globin mutations are evident in the neonate and then disappear as gamma globin synthesis wanes.

Thalassemias are due to absent or deficient synthesis of a normal globin chain, leading to a relative excess of the complementary or partner chain (Brancaleoni et al., 2016). For example, alpha thalassemias are due to diminished synthesis of alpha globin chains, leading to an excess of beta chains (or, in the fetus, of gamma chains). The excess beta chains form tetramers (hemoglobin H) that are unstable and can lead to hemolysis beyond infancy. The excess gamma chains also form tetramers (hemoglobin Bart's) that have an increased affinity for oxygen but do not cause hemolysis. In beta thalassemia, excess alpha globin chains accumulate, forming aggregates that injure the cell membrane, leading to hemolysis. In addition, the decrease in overall production of hemoglobin produces microcytic hypochromic erythrocytes.

Alpha Thalassemia

Neonatologists should be aware of the fetal/neonatal manifestations of alpha thalassemia. The more severe forms of alpha thalassemia are found in Southeast Asians, less commonly in individuals of Mediterranean origin, and are rare in Africans (Vichinsky, 2013). The molecular basis for alpha thalassemia involves deletion of one or more of the four alpha globin genes. Hemoglobin Constant Spring can also behave like a mild form of alpha thalassemia (He et al., 2016). The clinical severity of alpha thalassemia is determined by how many of the four alpha globin genes are absent. An infant can inherit none, one, or two alpha globin genes from each parent, giving rise to the following four clinical syndromes (Vichinsky, 2013):

1. *One-gene deletion. Silent carrier.* Deletion or nonfunction of one of the four alpha globin genes has no clinical or hematologic abnormalities. State metabolic screens sometimes identify small amounts of hemoglobin Bart's (gamma chain tetramers).
2. *Two-gene deletion. Alpha thalassemia trait.* Deletion or nonfunction of two of the four alpha globin genes, in *cis* (Asians) or *trans* (Africans), is associated with mild microcytic anemia, without hemolysis or reticulocytosis. These neonates will almost invariably have hemoglobin Bart's identified on their state hemoglobin screen.

3. *Three-gene deletion. Hemoglobin H disease.* When three of the four alpha globin genes are deleted or nonfunctional, a mild to moderate hemolytic anemia occurs, often aggravated by oxidant stresses just as in G6PD deficiency. The erythrocytes are hypochromic and microcytic and contain inclusions of hemoglobin H when appropriate staining is performed. Hemoglobin H Constant Spring disease can be a particularly severe syndrome, with up to one-third of neonates and infants requiring regular transfusions.

4. *Four-gene deletion. Homozygous alpha thalassemia.* Lack of all four alpha globin genes is associated with a severe intrauterine hemolytic anemia and hydrops fetalis, with massive hepatosplenomegaly and, in almost all instances, fetal demise (Bellini et al., 2015). The RBCs are very hypochromic, fragmented, and bizarre in shape, and erythroblastosis is present.

The diagnosis of the alpha thalassemia syndromes can be made during the newborn period by correlation of the clinical and hematologic appearance of the child with the amount of hemoglobin Bart's (tetramers of gamma chains). The large amount of hemoglobin Bart's found in the erythrocytes of homozygotes for alpha thalassemia contributes to the clinical severity of the syndrome because the increased oxygen affinity of this hemoglobin impairs oxygen release to the tissues. DNA-based diagnostic tests are available for prenatal diagnosis, which is often performed when a pregnancy at risk for a fetus with homozygous alpha thalassemia is identified.

Neonates with the silent carrier state or with an alpha thalassemia trait need no treatment for their condition. However, it can be helpful to determine the thalassemia status of other family members because this can inform genetic counseling (and prenatal diagnosis if indicated). Parents of neonates with hemoglobin H disease should be instructed to avoid oxidants that can cause hemolysis (the same list that is given to patients with G6PD deficiency). Although these infants are usually only mildly anemic, they can have severe episodes of hemolysis during infections or with exposure to oxidants. Fetuses with homozygous alpha thalassemia who are not spontaneously aborted are usually stillborn. A few affected children have been born alive and resuscitated or supported with in utero transfusion before delivery. A few have undergone bone marrow transplant, but the long-term outcome for such infants is quite uncertain.

Gamma Thalassemia

Large deletions within the beta globin gene cluster may remove both gamma globin genes as well as delta and beta globin genes. The resulting gamma–delta–beta thalassemia is lethal in the homozygous state but in the heterozygote produces a transient but moderately severe microcytic anemia in the newborn (Glader, 2013). Over the first few months the anemia resolves to a variable extent without specific therapy, and eventually the hematologic picture is that of a beta thalassemia trait. Several different gamma–delta–beta deletions have been reported.

Neonatal Polycythemia/Hyperviscosity and Methemoglobinemia

Polycythemia/Hyperviscosity

The definition of neonatal polycythemia is a statistical issue. The definition is met when the hematocrit, blood hemoglobin concentration, or RBC count (or all three) exceeds the 95th percentile upper reference interval for gestational age and postnatal age (Henry and

Christensen, 2015). Sometimes the upper reference interval is set at the 97.5th percentile. The higher cut-point for defining polycythemia is the most common for older children and adults. As detailed earlier in this chapter, the difference is that the adult reference intervals are generally derived from healthy adult volunteers, while the neonatal reference intervals are derived from clinically ordered tests on patients; thus the neonatal interval charges are more likely to contain abnormal (both low and high) values. On that basis a somewhat more restrictive definition (>95th percentile rather than >97.5th percentile) has become the convention.

Altitude relative to sea level is a significant consideration in defining polycythemia of adults and nonneonatal children. This is because at very high altitudes the relatively less oxygen (O₂) in inspired air results in a marrow compensation to produce higher hematocrit, blood hemoglobin concentrations, and RBC count. These physiologic adjustments compensate for the lower O₂ availability in the inspired air and permit a normal delivery of oxygen to tissues. Consequently, the hematocrit “cutoff” level that defines a patient as being polycythemic is much higher among those living at high altitude than it is among those living at sea level. This difference in altitude is less important, perhaps not important at all, in defining polycythemia of most neonates. Yancey et al. (1992) reported no differences in umbilical cord blood arterial or venous oxygen saturation values for births at 5900 feet above sea level (Fort Carson, Colorado) versus 87 feet above sea level. Reference intervals for hematocrit in newborns in Salt Lake City hospitals (Christensen et al., 2009; Jopling et al., 2009) (about 5000 feet above sea level) are essentially the same as those for newborns at sea level. However, perhaps at very high altitudes (>10,000 feet) fetal hematocrits are slightly higher, and thus for very high altitude nurseries, unique reference intervals might be needed to accurately define neonatal polycythemia.

In adult populations the definition of polycythemia depends on sex, because statistically, groups of males have higher hematocrits, hemoglobin levels, and RBC counts than women. Although some small studies suggested that male fetuses and neonates had higher hematocrits than their female counterparts, larger studies of matched populations of male and female newborns indicate no differences in hematocrit or hemoglobin level or RBC counts between the sexes. Therefore one set of reference ranges will suffice for both males and females.

It is important for clinicians to recognize that polycythemia is not synonymous with hyperviscosity and that not every neonate with polycythemia also has hyperviscosity or will benefit from a reduction transfusion procedure. Viscosity is the property of a liquid to resist changes in shape; for example, honey is more viscous than water. When the whole blood viscosity measurement of a neonate exceeds the appropriate 95th percentile upper reference interval for age, hyperviscosity is diagnosed. That laboratory-based definition of neonatal hyperviscosity implies that a Clinical Laboratory Improvement Amendments–approved clinical laboratory is available to perform a whole blood viscosity measurement and can perform this with a reasonable time and at reasonable cost. For some NICUs this is indeed the case, as it is for us in Salt Lake City, where ARUP Laboratories perform whole blood viscosity testing every day (Christensen et al., 2014b). However, when whole blood viscosity testing is not convenient, hyperviscosity can be inferred when a neonate with polycythemia has signs of hyperviscosity (Box 81.3). When signs of hyperviscosity are obvious, in a polycythemic neonate, obtaining a whole blood viscosity measurement might not be particularly important. But when clinical signs are subtle or absent, yet the hematocrit is greater than the 95th

percentile upper limit, hyperviscosity measurements can influence the decision about the risk–benefit analysis for reduction transfusion.

Neonatal polycythemia is usually caused by one of two conditions: increased intrauterine erythropoiesis or fetal hypertransfusion. Other causes seen in older children, such as arterial hypoxemia (cyanotic heart disease, pulmonary disease), abnormal hemoglobins, or hypersecretion of Epo by tumors, are rare, and primary polycythemia or polycythemia vera is virtually nonexistent in neonates. In normal term infants, delayed clamping of the umbilical cord for 3 minutes or more can sometimes lead to transfer of a sufficient amount of fetal blood so as to cause polycythemia. Placental insufficiency and chronic intrauterine hypoxia, as seen typically in SGA infants, can lead to an increase in Epo-mediated erythropoiesis.

As the hematocrit increases, blood viscosity increases exponentially. Oxygen transport, which is determined by both hemoglobin levels (i.e., oxygen-binding capacity) and blood flow, is maximal in the normal hematocrit range. At low hematocrits, oxygen transport is limited by reduced oxygen-binding capacity, whereas at higher hematocrits, reduction in blood flow secondary to hyperviscosity may similarly limit oxygen transport. At any given hematocrit, expansion of the blood volume beyond the normal level distends the vasculature, decreases peripheral resistance, and increases blood flow and, ultimately, oxygen transport.

Most polycythemic infants have no symptoms, particularly if the polycythemia becomes apparent only on routine neonatal screening. Symptoms, when present, are usually attributable to hyperviscosity and poor tissue perfusion or to associated metabolic abnormalities, such as hypoglycemia and hypocalcemia. Early signs include plethora, cyanosis, lethargy, hypotonia, poor suck and feeding, respiratory distress, and tremulousness. Complications can include cardiorespiratory distress, seizures, necrotizing enterocolitis, and renal failure. Because the elevated RBC mass increases the catabolism of hemoglobin, hyperbilirubinemia is common.

Methemoglobinemia

Methemoglobin (metHb) is derived from the oxidation of hemoglobin iron, whereby the iron is in the ferric (Fe³⁺) rather than the ferrous (Fe²⁺) state (Glader, 2013). Oxidized iron renders hemoglobin much less able to either bind or release oxygen. Thus when the concentration of metHb rises significantly, oxygen transport is reduced. Normally, small amounts of metHb are formed from hemoglobin constantly during the process of releasing

oxygen. The metHb that formed is then reduced through the action of erythrocyte nicotinamide adenine dinucleotide (NADH)-dependent metHb reductase, which is also called *cytochrome b5 reductase*. Thus normally the levels of metHb seldom exceed 1% of total hemoglobin. A second metHb reductase, dependent on NADPH as a cofactor, is also present in RBCs. This enzyme has little function under normal physiologic conditions, but it is greatly activated by the presence of certain redox compounds, such as methylene blue, forming the basis for the clinical treatment of methemoglobinemia.

Normal individuals can acquire methemoglobinemia after exposure to oxidizing chemicals. Neonates are particularly susceptible to this because HbF is more readily oxidized to the ferric state than is hemoglobin A and also because erythrocyte NADH-dependent metHb reductase activity is low during the first few months. Merely marking of the diapers of newborns with aniline dyes has caused methemoglobinemia. Drugs such as prilocaine, administered before birth to provide local anesthesia, can produce methemoglobinemia in both the mother and the infant. Although in most infants no increase in metHb levels follows the use of lidocaine–prilocaine cream (EMLA cream) to provide analgesia during circumcision, a few case reports of visible cyanosis caused by methemoglobinemia in infants treated with this cream have appeared (Tran and Koo, 2014). Perhaps the best known agent causing methemoglobinemia is nitrite, either present *de novo* in ingested material or generated by administration of nitric oxide to treat pulmonary hypertension (Davidson et al., 1998). Nitrates can be converted to nitrite by the action of intestinal bacteria. It is for this reason that well water or foods with a high nitrate content (e.g., cabbage, spinach, beets, carrots) can produce methemoglobinemia in infants (Glader, 2013). Accumulation of nitrate in the intestinal tracts of infants with diarrhea and acidosis or symptomatic dietary protein intolerance is thought to underlie the transient methemoglobinemia that occurs in these conditions.

Congenital methemoglobinemia can be the result of either inherited disorders of hemoglobin structure or a severe deficiency of NADH-dependent metHb reductase activity. The inherited abnormalities of hemoglobin structure that give rise to methemoglobinemia are known collectively as the *hemoglobin M disorders*. These are rare autosomal dominant defects caused by point mutations that alter a single amino acid in the structure of normal globin. The altered conformation favors the persistence of the ferric rather than the ferrous form of heme iron. Two of the mutations affect the alpha globin chain, three affect the beta globin chain, and two affect the gamma globin chain. Only the alpha and gamma globin chain mutations are associated with neonatal methemoglobinemia. Neonatal methemoglobinemia is transient when produced by one of the two gamma globin chain mutations, hemoglobin FM Osaka (Hayashi et al., 1980) or hemoglobin FM Fort Ripley (Glader, 1989), because the normal developmental switch from fetal to adult hemoglobin eliminates all but a trace of the mutant hemoglobin. Hemoglobin M heterozygotes inheriting alpha or beta globin mutations have lifelong cyanosis, but they are usually asymptomatic. The homozygous state is incompatible with life.

NADH-dependent metHb reductase deficiency is a rare autosomal recessive disorder. Heterozygotes are asymptomatic and do not have methemoglobinemia unless challenged by drugs or chemicals that cause methemoglobinemia. Homozygotes have lifelong metHb levels of 15%–40% and are cyanotic but otherwise asymptomatic unless exposed to toxic agents.

The cardinal clinical manifestation of methemoglobinemia is cyanosis not resulting from cardiac or respiratory disease. Cyanosis present at birth suggests hereditary methemoglobinemia, whereas that appearing suddenly in an otherwise asymptomatic infant is more consistent with acquired methemoglobinemia. The blood is dark and, unlike deoxygenated venous blood, does not turn red when exposed to air. Rapid screening for methemoglobinemia can be done by placing a drop of blood on filter paper and then waving the filter paper in air to allow the blood to dry. Deoxygenated normal hemoglobin turns red, whereas metHb remains brown. More accurate determination of metHb levels is accomplished in the blood gas laboratory by cooximetry or in the clinical laboratory with use of a spectrophotometer. Cyanosis is first clinically evident when metHb levels reach approximately 10% (1.5 g/dL), but symptoms attributable to hypoxemia and diminished oxygen transport do not appear until the levels reach 30%–40% of the total hemoglobin level. Death occurs at levels of 70% or greater. Methemoglobinemia is not associated with anemia, hemolysis, or other hematologic abnormalities.

Treatment with intravenously administered methylene blue (1 mg/kg as a 1% solution in normal saline) is indicated when metHb levels are greater than 15%–20%. Doses greater than 1 mg/kg should be avoided, because they may be toxic. The response to methylene blue is both therapeutic and diagnostic. MetHb levels decrease rapidly, within 1 to 2 hours, if methemoglobinemia is caused by a toxic agent or by a deficiency of NADH-dependent metHb reductase. In contrast, the hemoglobin M disorders do not respond to methylene blue. Reappearance of methemoglobinemia after an initial response to methylene blue suggests a deficiency of NADH-dependent metHb reductase or the persistence of an occult oxidant.

Treatment Considerations

Treatment of Anemia

The best practices in neonatal transfusion medicine are only beginning to be defined (Christensen et al., 2014c). Methods of preventing early anemia in VLBW neonates have been tested, such as delayed clamping of the umbilical cord or umbilical cord milking (stripping) and drawing the blood for initial laboratory blood studies of VLBW infants from otherwise discarded blood in the umbilical cord, not directly from the neonate. Guidelines to reduce phlebotomy-related losses of blood from VLBW neonates and the selected use of erythropoiesis-stimulating agents have also been favorably tested as complementary anemia-prevention approaches.

Regardless of the mechanism responsible for anemia of prematurity, exogenous Epo administered to preterm infants accelerates effective erythropoiesis (Aher and Ohlsson, 2014a, 2014b; Ohls et al., 2015). Metaanalysis of studies evaluating the use of “early” Epo administration and the use of “late” Epo administration to prevent and treat anemia of prematurity reveals a positive effect on decreasing transfusion requirements in preterm infants. In addition, beneficial neurodevelopmental effects of recombinant Epo administration have been reported in preterm infants (Ohls et al., 2013, 2014, 2016).

Pharmacokinetic studies of darbepoetin, a long-acting erythropoietic stimulator, have been conducted among neonates with anemia of prematurity, with the speculation that less frequent dosing and cost savings might render darbepoetin a more attractive alternative than rEpo for treatment of anemia of prematurity.

(Warwood et al., 2005, 2006a, 2006b; Patel and Ohls, 2015). Following subcutaneous and intravenous dosing, darbepoetin has a shorter terminal half-life in neonates than in adults. Intravenous dosing appears to be as effective as subcutaneous dosing.

One very basic issue that remains unsettled is at what level to keep the hemoglobin concentration during the NICU stay (Henry et al., 2015). It is not clear whether to keep an NICU patient's hemoglobin level as high as it would be in utero (often requiring multiple transfusions to do so) or to permit it to fall to considerably lower values, attempting to avoid or minimize transfusions. Attempts have been made to define the best hemoglobin range for NICU patients, but study findings are discordant. In a single-center study, Bell et al. (2005) randomized 100 neonates with birthweights below 1300 g (average birth weight 956 g) to maintain the hematocrit in a "higher range" versus a "lower range." Those with the hematocrit kept in the lower range received fewer transfusions (average of two fewer per patient) but may have been more likely to develop periventricular leukomalacia. In contrast, the Premature Infants in Need of Transfusion (PINT) study, a larger multicenter study involving 451 extremely low birth weight (ELBW) neonates (average birthweight 770 g), concluded that neonates randomized to having their hematocrit kept in the lower range had fewer transfusions but similar neurodevelopmental outcomes (Kirpalani et al., 2006). Longer-term follow-up of the Iowa cohort indicated that the restricted transfusion strategy resulted in better neurodevelopmental outcomes (McCoy et al., 2011; Nopoulos et al., 2011). Shorter-term (18- to 22-month) follow-up of the PINT study participants suggests that higher hemoglobin thresholds for transfusion may be beneficial to neurocognitive outcomes. These concepts are currently being tested by the Eunice Kennedy Shriver National Institute of Child Health and Human Development Neonatal Research Network with the Transfusion of Prematures (TOP) trial, where a planned 1824 infants will be randomized to have higher versus lower transfusion thresholds with a primary outcome of death or neurodevelopmental impairment at 22 to 26 months.

Various neonatal transfusion guidelines have been used in the last 2 decades, and research, including the TOP trial, is ongoing to determine the optimal strategy for administering RBC transfusions to preterm and term neonates. The strategy developed by the University of Utah and Intermountain Healthcare is shown in Table 81.7. When one is considering a transfusion in a preterm infant with a low hematocrit, it should be determined if the infant

needs an immediate increase in oxygen delivery to tissues. If so, then treatment consists of a transfusion of packed RBCs. If there is no evidence that an immediate increase in oxygen delivery is necessary, then treatment with erythropoiesis-stimulating agents might be considered. As the process of stimulating erythropoiesis requires at least 1 week to significantly impact the reticulocyte count and may not appreciably increase the hemoglobin concentration during that time, the infant should continue to be observed for signs consistent with anemia.

A method of reducing erythrocyte transfusions among a subset of preterm neonatal patients is to begin the administration of rEpo or darbepoetin to those with low hematocrits after the first 3 weeks of life. rEpo certainly stimulates erythropoiesis in such patients, although its combination with additional folate, iron, vitamin E, and vitamin B₁₂ may be superior to recombinant Epo alone. Haiden et al. (2006) achieved significantly greater success in preterm infants weighing less than 800 g (38% of infants not transfused) when vitamin B₁₂ at a dosage of 21 mg/kg per week subcutaneously was added to a regimen of Epo, iron, vitamin E, and folate. When combined with limited phlebotomy-related blood losses, this therapy shows promise in ELBW infants.

Another method of reducing erythrocyte transfusions to ill neonates is to delay clamping of the umbilical cord. A delay of 60 seconds can result in improved iron status, fewer transfusions, and perhaps superior neurodevelopmental outcomes. Placenta transfusions can be expedited by cord milking or stripping. The amount of blood in a 30-cm segment of umbilical cord is estimated in Fig. 81.7. Typically, stripping a segment of cord, then letting it fill, and restripping it about three or four times can be accomplished in about 15 seconds. This generally accomplishes a transfusion of a similar volume of fetal blood as would be transfused with delayed cord clamping for 60 seconds (Al-Wassia et al., 2015; Katheria et al., 2015).

Yet another method of reducing or postponing early erythrocyte transfusions among ELBW neonates is to draw the blood for the initial laboratory tests from the placenta not from the neonate (Christensen et al., 2011c; Baer et al., 2013; Christensen et al., 2014c; Carroll and Christensen, 2015; Henry et al., 2015). The initial blood tests of an ELBW neonate on admission to the NICU can include a blood culture, complete blood count, tests for type and crossmatch, metabolic screen, and tests for blood gas, electrolyte, and glucose levels. Sometimes other studies such as coagulation tests are also performed at or shortly following NICU admission.

TABLE 81.7

Intermountain Healthcare/University of Utah Guidelines for Red Blood Cell Transfusions for Newborns

These guidelines provide an “indication” where transfusions are generally thought to have benefits outweighing risks. The guidelines do not mandate that a transfusion must be ordered for all neonates with this “indication”; rather the guidelines are intended as reminders to consider a transfusion under those circumstances. Any order for blood products should always be accompanied by a note in the medical record stating the clinical reason for the transfusion.

| Condition | Indication | Treatment |
|--|--------------------------|----------------------------|
| ECMO, cyanotic heart disease, pulmonary hypertension | HGB <12 g/dL or HCT <36% | 15 to 20 mL/kg in 2 to 4 h |
| Ventilator or CPAP | HGB <10 g/dL or HCT <30% | |
| Supplemental O ₂ | HGB <8 g/dL or HCT <24% | |
| Stable in room air | HGB <7 g/dL or HCT <21% | |

CPAP, Continuous positive airway pressure; ECMO, extracorporeal membrane oxygenation; HCT, hematocrit; HGB, hemoglobin; O₂, oxygen.

The total blood volume needed for these baseline NICU laboratory studies can be 4 to 5 mL or more. In a 400-g to 500-g neonate, this can exceed 10% of the total blood volume.

The need for early transfusions in the NICU can be reduced by careful attention to phlebotomy blood volumes required during the first few days following delivery. Transfusions given during the first week or first 2 weeks are principally to replace phlebotomy-related blood losses for laboratory tests. Use of laboratory methods that minimize blood loss will reduce the need for early transfusions. Such methods include point-of-care monitors, point-of-care analyzers, and a concerted effort to use the smallest amount of blood possible for the laboratory studies needed (Widness et al., 2005).

Treatment of Hyperviscosity

Treatment of hyperviscosity is by isovolumetric partial exchange transfusion to reduce the RBC mass without inducing hypovolemia. When polycythemia is present but hyperviscosity is not, treatment is probably unnecessary. The purpose of partial exchange is to alleviate the signs of hyperviscosity, such as plethora, hypoglycemia, tachypnea, and tachycardia. Partial exchange transfusion is not likely to alleviate long-term neurodevelopmental delay found in some neonates with hyperviscosity. The reason for this relates to the underlying causes of neonatal hyperviscosity. When it is due to intrauterine hypoxia, with a resulting elevation in Epo concentration and a consequent increase in erythrocyte production, the effect of the hypoxia can have long-term adverse neurodevelopmental consequences that are unaltered by reduction transfusions. Also, another treatment concern is that reduction transfusion may increase the risk of necrotizing enterocolitis.

Our treatment guidelines are as follows:

- Diagnose polycythemia on the basis that the vascular (not a capillary) hematocrit or hemoglobin concentration exceeds the 97.5th percentile upper reference interval for the gestational and postnatal age.
- Diagnose hyperviscosity on the basis that the whole blood viscosity measurement exceeds the 97.5th percentile upper reference interval for the gestational age. If a whole blood viscosity measurement is not available, diagnose hyperviscosity on the basis of polycythemia *plus* signs of hyperviscosity—plethora, hypoglycemia, and tachycardia/tachypnea—with no other explanation.
- Consider partial exchange transfusion (also known as *isovolemic reduction transfusion*) to alleviate the signs of hyperviscosity.
- Perform the reduction transfusion by simultaneously withdrawing 10 mL of blood per kilogram while in another vessel (not arterial) infusing for each kilogram 10 mL of lactated Ringer solution or normal saline, which was prewarmed by placing the syringe containing the intravenous solution near the neonate under the radiant warmer. If the prerelation hematocrit exceeds 75%, use 15 mL/kg rather than 10 mL/kg as the exchange volume.

Neonatal Transfusion

RAVI MANGAL PATEL AND CASSANDRA D. JOSEPHSON

Disclosures: Cassandra Josephson is a consultant for Immucor and Biomet Zimmer. Ravi Patel has no conflicts of interest to disclose.

Grant Support: This study was supported by the National Institutes of Health. Ravi Patel received salary support from the National Heart, Lung, and Blood Institute (K23 HL128942). The National Institutes of Health had no role in (1) study design, (2) the collection, analysis, and interpretation of data, (3) the writing of the report, and (4) the decision to submit the paper for publication.

KEY POINTS

- The decision of when to administer red blood cell (RBC) transfusion may have an impact on long-term neurocognitive outcomes and may potentially influence short-term morbidity such as necrotizing enterocolitis.
- The optimal thresholds at which to transfuse RBCs are uncertain, although tolerance of hemoglobin values below the lower transfusion thresholds evaluated in randomized trials is not recommended.
- There is wide variation in the targeting of platelet thresholds, and it is unclear if prophylactic platelet transfusions in preterm neonates prevent serious hemorrhage.
- Prophylactic plasma transfusion is likely to have a minimal effect on prevention of intracranial bleeding in preterm infants, and newer measures such as thromboelastography may provide more precise data to guide the administration of plasma transfusion.
- Delaying clamping of the umbilical cord and minimizing phlebotomy-related blood losses are important cotreatment strategies in minimizing RBC transfusion exposure.

Overview

Blood transfusion is essential to modern neonatal intensive care and can be lifesaving, particularly for critically ill neonates or infants undergoing surgery. Blood components are necessary to carry and deliver oxygen to tissues, provide adequate preload to the heart to support cardiac output, and maintain a balance between hemostasis and coagulation to prevent both bleeding and thrombosis. In this chapter, specific blood component therapy and special circumstances in neonatal transfusion medicine will be reviewed.

Red Blood Cell Transfusion

Component

Red blood cells (RBCs) are the most commonly transfused component of whole blood. They are produced by centrifugation from whole blood or, less frequently, acquired directly from a donor by apheresis. Various storage solutions, such as citrate–phosphate–dextrose–adenine (CPDA-1) and additive–glucose–mannitol (e.g., AS-1, AS-3), contain anticoagulants and preservatives used to maintain RBCs at 4°C during storage. AS-1 and AS-3 units contain mannitol and adenine, which are associated with diuresis and renal toxicity respectively. Therefore RBCs stored in AS-1 and AS-3 should not be used for large-volume (≥ 20 mL/kg) transfusions.

Preparation

Preparation of RBCs for transfusion begins with donor assessment and ends with transfusion into the neonate. The goal is to assure blood safety and maximize efficacy and response to transfusion. Accurate RBC component and recipient identification are imperative for safety. More than 300 blood group antigens, from 35 blood group systems, have been discovered on RBCs ([Fasano and Chou, 2016](#)). Among these, the ABO and D (also known as rhesus [Rh]) blood groups are the most important in determining the compatibility of allogenic RBC transfusion. Infants can have four ABO blood types containing the corresponding A or B antigens on the RBC surface: group A, group B, group AB, or group O (no A or B antigens). In addition, infants can be D antigen positive or D antigen negative. Patient testing of the plasma or serum from either the infant or the mother must include ABO and D typing of their RBCs and a screen for unexpected RBC antibodies (indirect antiglobulin test). Before non-group type O RBCs are issued, the infant's plasma or serum is tested to detect passively acquired maternal anti-A or anti-B isohemagglutinins, which usually do not develop until more than 4 months of age. Importantly, crossmatch compatibility testing and repeated ABO and D typing, as is required for all patients older than 4 months, may be omitted during any hospitalization for an infant younger than 4 months, as long as any of the following criteria are met: (1) the antibody screen is negative; (2) the transfused RBCs are group O, ABO identical, or ABO compatible; or (3) the RBCs are either D negative or the same D type as those of the patient. Testing for the isohemagglutinins must also include the antiglobulin phase of testing at 37°C (body temperature). In the presence of an immunoglobulin

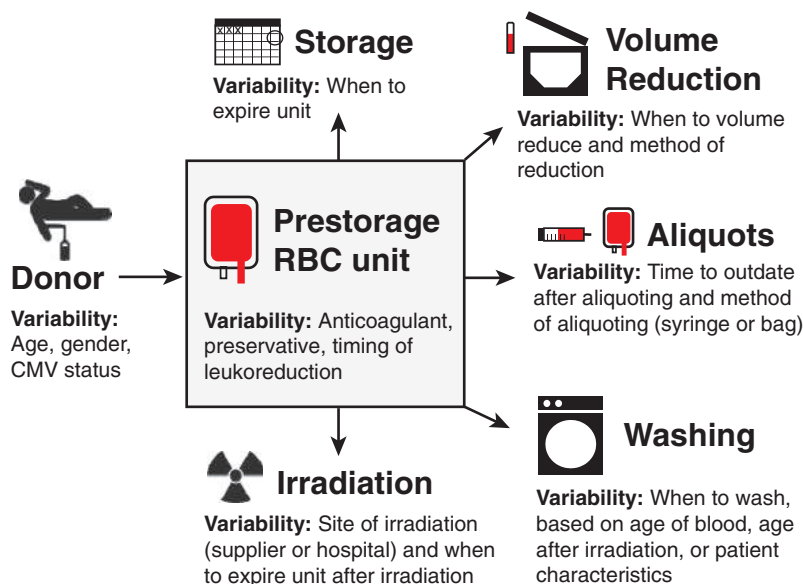

G (IgG) antibody, crossmatched, ABO-compatible RBCs are administered until the acquired antibody is no longer detected. Once RBC units have been properly selected, sterile aliquots from the parent unit are produced to more accurately provide volumes of RBCs dosed on the basis of the patient's weight. This can reduce the risk of transfusion-associated circulatory overload and also limit donor exposure–related infectious risks by repeatedly using the same RBC unit (Fung et al., 2013). Data suggest that 20 mL/kg transfusions in very low birth weight (VLBW) infants, compared with 10 mL/kg transfusions, lead to a greater increase in hematocrit without respiratory compromise (Paul et al., 2002). Although the optimal dose and duration of RBC administration are not known, transfusions should not run for longer than 4 hours. There is substantial variability in how blood centers and blood banks prepare RBCs (Fig. 82.1). This includes strategies to prevent cytomegalovirus (CMV) transmission (Josephson et al., 2014; AABB, *Clinical Transfusion Medicine Committee* et al., 2016), how and when RBCs are irradiated (Patel et al., 2015), when RBCs are unwashed (Keir et al., 2016), and what age of RBC units to use. The exclusive use of RBC transfusions from CMV-seronegative donors in VLBW infants has been shown to be associated with a very low estimated risk of transfusion-transmitted CMV infection of between 0.0% and 0.3% per unit of CMV-seronegative and leukoreduced blood (Josephson et al., 2014). Historically, the risk of transfusion-transmitted CMV (TT-CMV) infection from leukoreduced transfusions from CMV-untested donors has been reported to be higher than that from approaches using both CMV-negative donors and leukoreduction (Vamvakas, 2005). In the opinion of the authors, the safest approach for transfusion of VLBW infants is to use leukoreduced RBCs from CMV-negative donors. However, given the low risks of TT-CMV infection with improvements in modern leukoreduction techniques, use of leukoreduced blood from CMV-untested donors is an acceptably safe and low-risk alternative (Delaney et al., 2016; Strauss, 2016). Importantly, RBC transfusion

should not be delayed if CMV-negative blood is unavailable, and CMV-untested blood should be used given the relatively low risk of TT-CMV infection.

Many centers limit the age of RBCs transfused into neonates and infants (Fung et al., 2010; Josephson et al., 2015). The maximum storage duration depends on the type of storage solution, with 35 days for CPDA-1 units and 42 days for AS-1 and AS-3 units. Recent randomized trials have provided high-level evidence regarding the safety of using stored, older RBC units. The Age of Red Blood Cells in Premature Infants (ARIP) trial randomized VLBW infants to receive fresh blood (mean 5 days) versus standard issue blood (mean 15 days) and found no difference in a composite of mortality or morbidity between groups (Fergusson et al., 2012). Similar trials in adults have produced concordant findings (Lacroix et al., 2015; Steiner et al., 2015). However, the age of RBC units may not account for other donor RBC characteristics, such as storage solutions and irradiation (Patel and Josephson, 2013).

Indications

Common indications for RBC transfusion include anemia, bleeding, and cardiorespiratory compromise. Extremely preterm infants are among the most highly transfused populations in medicine, with more than 90% of extremely low birth weight infants weighing 1000 g or less at birth receiving at least one RBC transfusion during their neonatal intensive care unit (NICU) stay (Maier et al., 2000). In addition, 60% of VLBW infants will undergo RBC transfusions during hospitalization. Studies of RBC transfusion approaches in this population have yielded mixed results. Two clinical trials have compared the efficacy of RBC transfusion using liberal (high hemoglobin threshold) versus conservative (low hemoglobin threshold) transfusion strategies (Bell et al., 2005; Kirpalani et al., 2006), and two trials are ongoing, the Transfusion of Prematures (TOP) trial (Kirpalani et al., 2016) and the Effects

TABLE 82.1 Red Blood Cell Transfusion Thresholds for Preterm Infants in Randomized Trials^a

| | | Iowa Trial (Bell et al., 2005) | PINT Trial (Kirpalani et al., 2006) | TOP Trial | ETTNO Trial |
|-------------|-------|--------------------------------------|---|--------------|----------------|
| Liberal | Upper | 15.3 | 13.5 | 13.0 | 13.7 |
| | Lower | 10.0 | 8.5 | 10.0 | 9.3 |
| Restrictive | Upper | 11.3 | 11.5 | 11.0 | 11.3 |
| | Lower | 7.3 | 7.5 | 7.0 | 7.0 |

^aThresholds are hemoglobin values in grams per deciliter, and differences between upper and lower thresholds within each transfusion arm reflect the range based on an infant's respiratory illness severity and postnatal age. See the text for additional information on the trials.

ETTNO, Effect of Transfusion Thresholds on Neurocognitive Outcome of Extremely Low Birth Weight Infants; PINT, Prematures in Need of Transfusion; TOP, Transfusion of Prematures.

of Transfusion Thresholds on Neurocognitive Outcome of Extremely Low Birth Weight Infants (ETTNO) trial (ETTNO Investigators, 2012) (Table 82.1). In the Prematures in Need of Transfusion (PINT) trial, a lower hemoglobin transfusion threshold resulted in a nonsignificant increase in neurodevelopmental impairment at 18–21 months (odds ratio [OR] 1.74, 95% confidence interval [CI] 0.98–3.11), which was significantly higher in a post hoc analysis with a more inclusive measure of neurodevelopmental impairment (Whyte et al., 2009). As RBC transfusions are sources of parenteral iron, fewer RBC transfusions using lower hemoglobin transfusion thresholds without appropriate enteral iron supplementation may increase the risk of iron-deficiency anemia, which is associated with adverse long-term neurodevelopmental outcomes (Lozoff et al., 1991; Lozoff and Georgieff, 2006). Among participants followed up at 12 years of age in a trial in Iowa, those who were more liberally transfused as a result of higher hemoglobin transfusion thresholds had lower brain volumes when compared with those randomized to lower hemoglobin thresholds with conservative transfusion (Nopoulos et al., 2011). Recent trends suggest an increasing use of conservative transfusion thresholds to decrease RBC exposure (Ekhaguere et al., 2016), mirroring patient blood management approaches in adults designed to minimize blood exposure (Shander et al., 2012). The outcomes of these studies are discussed later.

For more mature preterm and term infants, transfusion approaches are largely based on expert opinion owing to the lack of randomized trials. In select populations of infants, such as those undergoing surgery, hematocrit thresholds of 40% or higher may be desired (Goobie et al., 2016). By contrast, asymptomatic preterm infants may tolerate a hemoglobin level of 7.0–7.5 g/dL before needing RBC transfusion (Table 82.1). In neonates in whom there is not an ongoing source of blood loss, iron supplementation or erythropoiesis-stimulating agents may be sufficient to help restore RBC volume. Additional information to guide RBC transfusion will likely to be provided by ongoing large, multicenter trials that are evaluating the relative risks and benefits of conservative versus liberal RBC transfusion thresholds in neonates. However, additional studies are needed to guide appropriate thresholds in term infants, particularly among neonates undergoing surgery (Goobie et al., 2016), including cardiac surgery (Wilkinson et al., 2014) and those

TABLE 82.2 Risk of Transfusion-Transmitted Infections in the United States

| Infection | Estimated Risk |
|------------------|---|
| HIV | 1 in 2,135,000 |
| Zika | None reported in United States |
| Ebola | None reported in United States |
| CMV ^a | Historically estimated risk up to 1%–3% for leukoreduced RBC transfusions from CMV-untested donors, although likely substantially lower (Seed et al., 2015). For RBC products from CMV-negative donors, estimated risk of 0% (95% CI 0.0%–0.3%) |
| Hepatitis B | 1 in 277,000 |
| West Nile virus | 1 in 350,000 |
| Malaria | 1 in 1,000,000 to 5,000,000 |

^aEstimates of cytomegalovirus (CMV) infection risk are based on data from Josephson CD, Callendo AM, Easley KA, et al. Blood transfusion and breast milk transmission of cytomegalovirus in very low-birth-weight infants: a prospective cohort study. *JAMA Pediatr.* 2014;168:1054–1062; and Seed CR, Wong J, Polizzotto MN, Faddy H, Keller AJ, Pink J. receiving extracorporeal membrane oxygenation support (Jackson et al., 2014).

Risks of Red Blood Cell Transfusion

The risks of blood component therapy, including RBC transfusion, are reviewed here. However, many of the immunologic and nonimmunologic risks discussed are based on studies in adult transfusion recipients and have not been adequately studied in the neonatal population.

Immunologic Complications

Historically, the primary risk of blood transfusion has been infection. However, current estimates of the risk of transfusion-transmitted infections suggest current donor selection and postdonation diagnostic testing strategies reduce the risk to below 1 in 100,000 and often below 1 in 1,000,000 for most infections (Table 82.2; Bihl et al., 2007). Acute immunologic complications of transfusion include hemolytic transfusion reactions, immune-mediated platelet destruction, febrile nonhemolytic reactions, allergic reactions, anaphylaxis, and transfusion-related acute lung injury (TRALI) (Food and Drug Administration, 2014). Formation of antibodies to ABO blood group antigens (anti-A and anti-B IgM and IgG types) typically occurs after 3 to 4 months of age (Fong et al., 1974). Therefore transfusion reactions related to ABO blood group incompatibility are less likely to occur in neonates. Delayed immunologic complications include delayed hemolytic reactions, alloimmunization to white blood cells, RBCs, and platelet antigens in blood components, posttransfusion purpura, and transfusion-associated graft-versus-host disease. Transfusion-related immunomodulation is a potential entity described in adults that involves

immunosuppressive effects of blood transfusion, which may be beneficial in solid-organ transplant but also can potentially increase the risk of infection and malignancy (Vamvakas and Blajchman, 2007). However, many of the studies on transfusion-related immunomodulation (TRIM) were done in an era before leukoreduction, and TRIM has not been investigated in neonates.

Transfusion-Related Acute Lung Injury

Although TRALI has not been well studied in neonates and infants, it is one of the most severe complications of blood component transfusion, largely caused by substances in plasma and platelet components, but can also occur after RBC transfusion. The cause of TRALI is grouped into immune and nonimmune types. In adults, immune TRALI is estimated to occur in 1 per 5000 transfusions, with case-fatality rates of 6%–9% among those affected (Bux, 2005). However, the incidence and risks of TRALI in neonates are unclear. Immune-TRALI is suspected to be due to substances within transfused blood products that elicit an immune response, such as HLA and granulocyte-binding alloantibodies. Nonimmune TRALI is thought to occur following stored platelet and RBC transfusions although is more benign than immune TRALI and is thought to be mediated by biologically active lipids.

Nonimmunologic Complications

Infection

Viral, bacterial, parasitic, or prion infections are possible from blood transfusion. Donor screening by history questionnaire, infectious testing, and donor deferral substantially reduces the risk of these infections but does not entirely eliminate them. Additionally, there is the potential for yet undiscovered infections to be transmitted through transfusion, as occurred with human immunodeficiency virus (HIV) among hemophilia patients in the 1980s (Hilgartner, 1987). Donor screening based on guidance from the Food and Drug Administration (FDA) (Circular of Information Task Force, 2016) involves testing the donor's ABO group and Rh type, including testing for a weak D antigen. Infectious testing is based on FDA-licensed tests and involves screening patients for HIV, hepatitis B virus, hepatitis C virus, Human T-lymphotropic virus I/II, West Nile virus, syphilis, and *Trypanosoma cruzi*, the cause of Chagas disease. For HIV, hepatitis C virus, and West Nile virus, nucleic acid testing is performed. Donors can also be screened for CMV, which can be much higher in more southern geographic locales and lower in more temperate and cooler regions, causing a wide variation in seroprevalence of donors of 40%–80% in different regions of the United States. This circumstance leads to variation among blood centers in the use of a CMV donor testing strategy to prevent CMV transmission.

Emerging pathogens such as Zika virus and Ebola virus highlight the residual risk of infections (Motta et al., 2016), including those that are yet to be identified. This is particularly relevant given global travel and the effect of epidemics such as dengue (Stramer et al., 2012) and chikungunya (Gallian et al., 2014) on transfusion medicine. Pathogen reduction offers an alternative that has the potential to increase the safety of the blood supply and has been recently approved by the FDA in the United States for use with plasma and platelet transfusions (Snyder et al., 2015). Clinical trials evaluating pathogen-reduction technologies for whole blood and RBCs are ongoing (Snyder et al., 2015). Pathogen inactivation works by combining ultraviolet irradiation with photosensitizers, such as psoralen, that damage pathogen nucleic acids, preventing replication and host infection. This can work for a wide range of viruses, bacteria, parasites, and other pathogens. In addition, this

technology can be used to reduce the risk for emerging infections, particularly when donor testing strategies are not available or fully implemented. However, pathogen reduction does not inactivate all pathogens, such as hepatitis A virus and hepatitis E virus. In addition, pathogen reduction is contraindicated for infants treated with certain phototherapy devices, because of the potential reaction between the psoralen additive and ultraviolet light from phototherapy that can lead to skin erythema (Circular of Information Task Force, 2016).

Transfusion-Associated Circulatory Overload

Large-volume (>20 mL/kg) RBC transfusions may place the infant at risk of transfusion-associated circulatory overload (TACO) that can lead to congestive heart failure and pulmonary edema. Patients with severe anemia without acute bleeding may require slow correction of anemia with RBC transfusion to reduce the risk of TACO. Additionally, certain subsets of neonates, such as those with fetal anemia and hydrops fetalis, may need isovolumetric RBC transfusion using an exchange transfusion. In this procedure, RBCs without whole blood reconstitution with plasma are administered, and whole blood is removed from the patient. Whole blood exchange transfusion for hemolytic disease of the fetus and newborn is discussed later in this chapter.

Hypothermia

Large-volume RBC transfusions can increase the risk of hypothermia because of RBC unit storage at 4°C. Thus blood warmers in the setting of large-volume or massive transfusion are indicated. The possibility of hypothermia resulting from transfusion should also be monitored in operative transfusions, when patients may have acute bleeding requiring rapid large-volume transfusions, coupled with potential cold stress from the operating room environment.

Metabolite Derangements

Electrolyte abnormalities can occur following RBC transfusion because of additive solutions in donor RBCs that contain mannitol (AS-1), a diuretic, and citrate (CPDA-1, AS-3), a calcium chelator, which can lead to hypocalcemia. This is particularly of concern in infants receiving massive transfusion or exchange transfusion. Additional risks include changes in pH and hyperkalemia or hypokalemia, particularly among patients with impaired renal function in the setting of massive transfusion. Washing of RBCs may reduce the risk of hyperkalemia.

Fatal Transfusion Reactions

Although rare, fatal reactions can result from any of the complications previously discussed and should be reported to the FDA. Historically, acute hemolysis from ABO-incompatible transfusions was the leading cause of deaths from blood transfusion (Sazama, 1990), although these are now uncommon because of improvements in blood banking practices and the lack of antibodies to blood group antigens in neonates in the first few months of life (Fong et al., 1974). Currently, TRALI is the most frequent cause of acute transfusion fatality among all blood recipients, accounting for 37% of deaths. However, there is uncertainty if this complication occurs in neonatal patients (Food and Drug Administration, 2012). Transfusion-transmitted bacterial sepsis is the third most common cause of reported transfusion-related fatalities, with more than two-thirds of infections caused by gram-negative organisms. Although a number of organisms have been reported, *Klebsiella pneumoniae*, *Escherichia coli*, and *Staphylococcus epidermidis* are the

three most common organisms, all attributed to platelet transfusion (Hillyer et al., 2003; Niu et al., 2006).

Platelet Transfusion

Component

Two types of platelet units are available in the United States, platelet concentrates (known as *random-donor* or *whole blood–derived platelets*) and apheresis platelets, known as *single-donor platelets*. Platelet concentrates are produced from whole blood drawn from a donor, whereas single-donor platelets are collected via an apheresis technique that returns the remaining whole blood components to the donor. These two methods of platelet collection yield distinctly different numbers of platelets per unit. One platelet concentrate contains approximately 7×10^{10} platelets, in contrast to one single-donor apheresis platelet concentrate with 3×10^{11} to 6×10^{11} platelets per unit. Pooling of five to eight platelet concentrates from different donors is required to equal the same amount of platelets in an apheresis platelet unit. Platelets have a short shelf life (limited to 5 days) and are stored at room temperature and preserved with constant, gentle agitation.

Indications

Platelet transfusions, typically dosed at 10 to 15 mL/kg, are nearly always administered prophylactically in the setting of thrombocytopenia, defined as a platelet count of less than 150,000/ μ L, or in response to severe bleeding. Thrombocytopenia is a common occurrence in neonates requiring intensive care, affecting an estimated 18%–35% of neonates on NICU admission and close to 70% of extremely low birth weight infants (Sparger et al., 2016). However, only a fraction of these infants receive platelet transfusions, estimated to be used in 5%–9% of infants cared for in US NICUs. There is considerable debate as to the appropriate prophylactic platelet transfusion thresholds for neonates, with wide variation in practices (Josephson et al., 2009; Cremer et al., 2011). Only one randomized trial in preterm infants evaluated the use of platelet transfusion to maintain a platelet count of 150,000/ μ L or greater, compared with standard practice, and found no significant difference in the severity of intraventricular hemorrhage (IVH) between treatment arms (Andrew et al., 1993). A more recent multicenter observational study of VLBW infants in six US NICUs found wide variation in platelet transfusion thresholds for transfusion, ranging from 10,000/ μ L to 139,000/ μ L in the first week of life and from less than 10,000/ μ L to more than 150,000/ μ L after the first week of life. The most common thresholds were 80,000/ μ L to 89,000/ μ L in the first 7 days of life and 40,000/ μ L to 49,000/ μ L after the first 7 days of life. The authors found platelet transfusion, after controlling for the severity of thrombocytopenia, was not associated with a lower risk of IVH. Complicating the assessment of platelet threshold and risk of bleeding are contributors to platelet dysfunction, such as nonsteroidal antiinflammatory medications, acidosis, or concomitant coagulopathy (Setzer et al., 1982), that can influence the risk of bleeding.

Risks

One of the major risks of platelet transfusions is bacteria sepsis, although this is relatively uncommon, with an estimated occurrence of 1 in every 100,000 platelet transfusions. Approximately 1 in every 3000 platelet units contains clinically relevant bacteria

concentrations (Snyder et al., 2015). Currently in the United States it is required that all platelet products be bacterially tested before release from the blood donor center. Pathogen inactivation is a potential approach to decrease this residual risk even further, although the effects of this approach on transfusion of platelets into immature neonates require additional study given the still relatively low risks of platelet transfusion–associated sepsis.

Plasma and Cryoprecipitate Transfusion

Components

Plasma, is the aqueous, acellular portion of whole blood and includes albumin, the most abundant of the plasma proteins, along with complement (predominantly C3), enzymes, transport molecules, Igs (γ -globulins), and coagulation factors. The coagulation factors in plasma include (1) fibrinogen; (2) factor XIII; (3) von Willebrand factor; (4) factor VIII, primarily bound to its carrier protein von Willebrand factor (\sim 100 ng/mL); and (5) vitamin K–dependent coagulation factors II (prothrombin), VII, IX, and X. Plasma products, fresh frozen plasma (FFP), or F24 plasma is mainly produced from whole blood and less frequently from plasmapheresis collections. FFP is frozen within 6 to 8 hours of collection, while F24 plasma is frozen within 24 hours of collection. Cryoprecipitate is an insoluble precipitate that is formed by the thawing of FFP and then the refreezing of it in 10 to 15 mL of plasma within 1 hour. This produces a product with high concentrations of factor VIII (80–150 U/unit), von Willebrand factor (100–150 U/unit), fibrinogen (\sim 250 mg/unit), factor XIII (150–250 U/unit), and fibronectin (\sim 2 mg/mL). Cryoprecipitate can be stored at temperatures of -18°C or lower and can be maintained for up to 1 year.

Indications

Plasma transfusions are used in up to 15% of NICU patients for a variety of indications, most often to treat or prevent bleeding in the setting of coagulopathy or disseminated intravascular coagulation (Keir and Stanworth, 2016). Additionally, plasma transfusion may be used as a colloid to increase intravascular volume, including situations in which low plasma oncotic pressure is suspected or patients have not responded to crystalloid therapy. However, there is wide variation in the use of plasma transfusion, and this may be related to variation in the assessment of coagulation and treatment of abnormal coagulation function studies (Chaudhary and Clarke, 2008), with increasing coagulation testing associated with more frequent use of plasma transfusion (Catford et al., 2014). The treatment of abnormal coagulation tests with plasma transfusion is often used in preterm infants, despite the lack of evidence to support an association between abnormal coagulation values in the first week of birth and serious hemorrhage, including IVH (Christensen et al., 2014). No contemporary clinical trials exist to guide the use of plasma transfusion in neonates, particularly as it relates to the prevention of bleeding. One randomized trial compared the prophylactic use of plasma compared with dextrose infusion or gelatin plasma (Gelo-fusine) and found no beneficial effect of early plasma transfusion with regard to death or cranial ultrasound scan abnormality (Northern Neonatal Nursing Initiative [NNNI] Trial Group and Elbourne, 1996). Cryoprecipitate is used to treat or prevent bleeding in infants with acquired hypofibrinogenemia (fibrinogen level <100 or 150 mg/dL) or as part of a massive transfusion protocol, as we discuss later in this chapter.

A single unit of cryoprecipitate usually contains 15 to 20 mL, and infants are typically transfused with 2 mL/kg or 0.5 unit for the average term infant weighing 3.5 kg.

Risks

The risks of plasma transfusions include TRALI, as mentioned previously, and infection. In addition, two studies have reported an increased risk of thrombosis among neonates (Maruyama et al., 2012) and children (Puetz et al., 2012) who received plasma transfusion. In the study by Maruyama et al. (2012), a total dose of FFP of more than 50 mL/kg in the first 5 days after birth was associated with an increased risk of venous thrombosis (adjusted OR of 5.9, 95% CI 1.1–41.8). Potentially, the use of thromboelastography, which measures multiple aspects of clot formation, strength, and fibrinolysis, may provide a more precise measure of coagulation to better guide the use of plasma transfusion in neonates (Sewell et al., 2016).

Special Circumstances

Massive Transfusion

Massive transfusion may be required in neonates with large-volume blood loss. On the basis of evidence from adults and children, the use of massive transfusion protocols with balanced ratios of blood products (RBCs, plasma, platelets, cryoprecipitate) may decrease the adverse effects of massive transfusion, particularly on the ability of the neonate to maintain hemostasis (Diab et al., 2013). In addition, the risks of transfusion previously discussed, such as metabolic complications or TACO, are increased in massive transfusion and require close monitoring. The appropriate ratio of blood products is uncertain, but studies (Hendrickson et al., 2012; Diab et al., 2013) have suggested use of a 1 : 1 ratio of RBCs and FFP, with additional alternating use of platelet and cryoprecipitate transfusions. In adults, the use of whole blood among trauma patients requiring massive transfusion has been evaluated and may be associated with better outcomes (Repine et al., 2006), but this has not been sufficiently evaluated in preterm infants. The use of fresh whole blood for cardiopulmonary bypass priming has no advantage over the use of a combination of products during surgery for congenital heart disease, with whole blood priming associated with an increased length of stay and more fluid overload (Mou et al., 2004).

Exchange Transfusion

The indications for exchange transfusion include severe hyperbilirubinemia, often in the setting of hemolytic disease of the fetus and newborn with ABO or Rh incompatibility or other minor RBC antigen–antibody incompatibilities with the mother, as well as anemia with fluid overload (e.g., hydrops fetalis) or hemochromatosis. Exchange transfusion is a relatively uncommon treatment following the introduction of Rh₀(D) immune globulin prenatally administered to the mother and intensive phototherapy for the infant. In one series, only 5 of 111,009 infants in a cohort from California NICUs received exchange transfusion for severe hyperbilirubinemia (bilirubin level >30 mg/dL) (Newman et al., 2003), and more recent data estimate this may be as low as 1.9 per 100,000 live births (Bhutani et al., 2016). For infants with severe hyperbilirubinemia, exchange transfusion is the most effective method of removing bilirubin rapidly, while simultaneously removing and

diluting out the offending antibody and RBC antigen target for the antibody. Typically, a double-volume exchange transfusion is recommended (Thayil and Milligan, 2006). This involves removing twice the estimated amount of circulating blood volume (70–80 mL/kg for term infants, 90–100 mL/kg for preterm infants) and replacing it with RBCs reconstituted with plasma, to a target hematocrit of the infant, in 1 to 3 hours. The RBCs should be leukoreduced, and, if they are going to a fetus for intrauterine transfusion, they should be irradiated. Small volumes, 5 mL/kg or less, with absolute aliquot volumes ranging from 5 to 20 mL, are exchanged serially, with each exchange occurring in several minutes. This procedure replaces approximately 85% of native circulating RBCs.

The most common risks following exchange transfusion are hypocalcemia (estimated to occur in 29%–38% of infants), thrombocytopenia (38%–44%), and infection (Keenan et al., 1985). Less common risks include catheter-related complications, thrombosis, bleeding, hypothermia, necrotizing enterocolitis, and cardiac arrhythmia. The historical risk of death from exchange is reported to be 3 per 1000 procedures (0.3%), although the current modern-era risk is difficult to estimate given the infrequent use of this therapy and differences in patient populations of infants undergoing exchange transfusion. In addition to double-volume exchange transfusions, partial exchange transfusions involve removing whole blood from a patient and replacing this with an equal volume of colloid or crystalloid. This is often done in response to polycythemia (hematocrit ≥65%–70%), although the benefit of partial exchange transfusions in reducing complications from polycythemia has not been well established (Ozek et al., 2010).

Intravenous Immune Globulin

Intravenous immune globulin (IVIG) therapy is a therapy using pooled Ig from multiple donors, often several hundred. In neonates, the most common indication is treatment of hemolytic disease of the fetus and newborn that is refractory to intensive phototherapy (AAP Subcommittee on Hyperbilirubinemia, 2004). IVIG works by blocking Fc receptors in the splenic reticuloendothelial system from destroying RBCs or platelets that are bound to maternal circulating antibodies, although the exact mechanisms are not clear. Treatment with IVIG decreases the risk of exchange transfusion and, among those receiving exchange transfusion, decreases the risk of subsequent exchange transfusion (Alcock and Liley, 2002). However, the effect of IVIG in studies with a low risk of bias shows no clear benefit (Louis et al., 2014). Overall, IVIG is well tolerated and has been extensively studied in the treatment of sepsis (Ohlsson and Lacy, 2013). However, hypotension is a common risk, and the risk can be reduced by decreasing the infusion rate (Katz et al., 2007). In addition, rare risks, including viral infection (Fasano, 1995) and necrotizing enterocolitis (Figueras-Aloy et al., 2010), have been reported, although in a systematic review and metaanalysis, no serious adverse effects of IVIG were identified (Ohlsson and Lacy, 2013).

Neonatal Alloimmune Thrombocytopenia

Neonatal alloimmune thrombocytopenia (NAIT) is a rare disorder that can lead to severe bleeding, including intracranial hemorrhage, in the fetus or neonate. Thrombocytopenia results from maternal alloimmunization against paternally derived platelet antigens, most commonly human platelet antigen (HPA)-1a (Shulman et al., 1962), although more than 27 different HPAs have been associated

with NAIT. NAIT is estimated to occur in approximately 1 per 1000 live births (Dreyfus et al., 1997). Typically, the mother is negative for HPA-1a and often, but not always, positive for anti-HPA-1a antibodies (Kjeldsen-Kragh et al., 2007). The fetus is HPA-1a positive, inheriting the gene from the father. Pregnant women become sensitized to the platelet antigen, resulting in transplacental passage of antiplatelet antibodies that cause immune-mediated destruction of platelets and thrombocytopenia. Severe hemorrhage is estimated to occur in 10 per 100,000 neonates, commonly occurring before birth (Kamphuis et al., 2014). Therefore prenatal IVIG treatment has been investigated and has been found to increase fetal platelet counts (Bussel et al., 1988), although the beneficial effect on reducing intracranial hemorrhage is unclear. If NAIT is diagnosed in an infant, future pregnancies typically undergo close monitoring, with testing of the father and, if indicated, the fetus. After birth, treatment involves transfusion using platelets negative for the offending paternal antigen obtained from the mother and washed or from a random donor. IVIG may also be used to decrease antibody-mediated platelet clearance. For most infants with NAIT, thrombocytopenia resolves over time as the passive antibody degrades (Bassler et al., 2008). Additional information about NAIT is given in Chapter 80.

Decreasing the Need for Red Blood Cell Transfusion

Anemia is nearly universal in extremely preterm infants (Widness, 2008), largely owing to phlebotomy-related blood losses (Rosebraugh et al., 2013). The effect of erythropoiesis-stimulating agents, such as erythropoietin and darbepoetin, on reducing RBC transfusion and donor exposure has been modest (Aher and Ohlsson, 2014; Ohlsson and Aher, 2014), although recent studies show promising beneficial effects of erythropoiesis-stimulating agents on long-term neurocognitive outcome in extremely preterm infants (Ohls et al., 2013, 2014), and additional large, multicenter trials are ongoing (Juul et al., 2015). Strategies to reduce phlebotomy-related blood losses (Carroll and Widness, 2012) are important aspects of patient blood management. Placental transfusion from delayed cord clamping or cord milking (Rabe et al., 2012) is another strategy to decrease the need for RBC transfusion (Rabe et al., 2009) and improve outcomes (Ghavam et al., 2014; Andersson et al., 2015) and should be considered as part of an institutional transfusion protocol.

Neonatal Leukocyte Physiology and Disorders

JOHN T. BENJAMIN, BENJAMIN A. TORRES, AND AKHIL MAHESHWARI

KEY POINTS

- The neonate and the young infant depend primarily on the innate immune system for host defense. With limited prior exposure to infectious and environmental antigens, the adaptive immune arm is still in a phase of structural and functional development.
- Neutropenia is frequently encountered during the neonatal period.
- Neonatal neutrophils show a wide range of functional deficiencies in movement, phagocytosis, and microbial killing.
- With the exception of a few deficiencies, neonatal monocytes and macrophages are functionally comparable to their counterparts from adults.
- Neonatal T-cell and B-cell populations are still developing. Several adaptive mechanisms, such as the presence of B1 cells that can function without assistance from T cells and the production of immunoglobulins with polyspecific antigen binding, are unique to the neonate and partially mitigate the deficiencies in adaptive immunity.
- The innate lymphoid cells are a recently described, exciting new subset in innate immunity that are likely to play a major role during the neonatal period and early infancy.

This chapter presents an overview of neonatal leukocyte physiology and quantitative and qualitative disorders of leukocytes. Topics include the normal physiology and defects associated with neonatal hematopoiesis, neutrophils, monocytes, lymphocytes, dendritic cells (DCs), and innate lymphoid cells (ILCs) (Fig. 83.1). Novel therapeutic approaches are also discussed.

Neutrophil Physiology and Function

Ontogeny

Neutrophils are an important line of defense in the cellular innate response (see Fig. 83.1). The life cycle of a neutrophil can conceptually be divided into three phases, representing time spent in (1) marrow, (2) blood, and (3) tissues. The earliest neutrophilic precursors, myeloblasts, promyelocytes, and myelocytes, are capable of cell division and thus are referred to as the *neutrophil proliferative pool* (NPP). In later stages of maturation, neutrophils lose their ability for cell division. These metamyelocytes, bands, and segmented

neutrophils continue to differentiate in situ and constitute the neutrophil storage pool (NSP). In adults the NSP is a sizeable reservoir of neutrophils that can be rapidly mobilized into the bloodstream when needed. However, the NSP is relatively much smaller in the midgestation fetus and preterm infant and can be readily exhausted during sepsis. In adult rats, the NSP contains about 6×10^9 cells per kilogram. In contrast, the rat NSP at 19 days' gestation contains only about 0.9×10^9 cells per kilogram, which expands marginally to 1.2×10^9 cells per kilogram at term (21 days). Unlike in fetal and newborn rodents, in whom the liver and spleen house a significant fraction of the NPP and NSP (Erdman et al., 1982), neutrophil production and storage in human neonates occur primarily in the bone marrow (Calhoun et al., 1996).

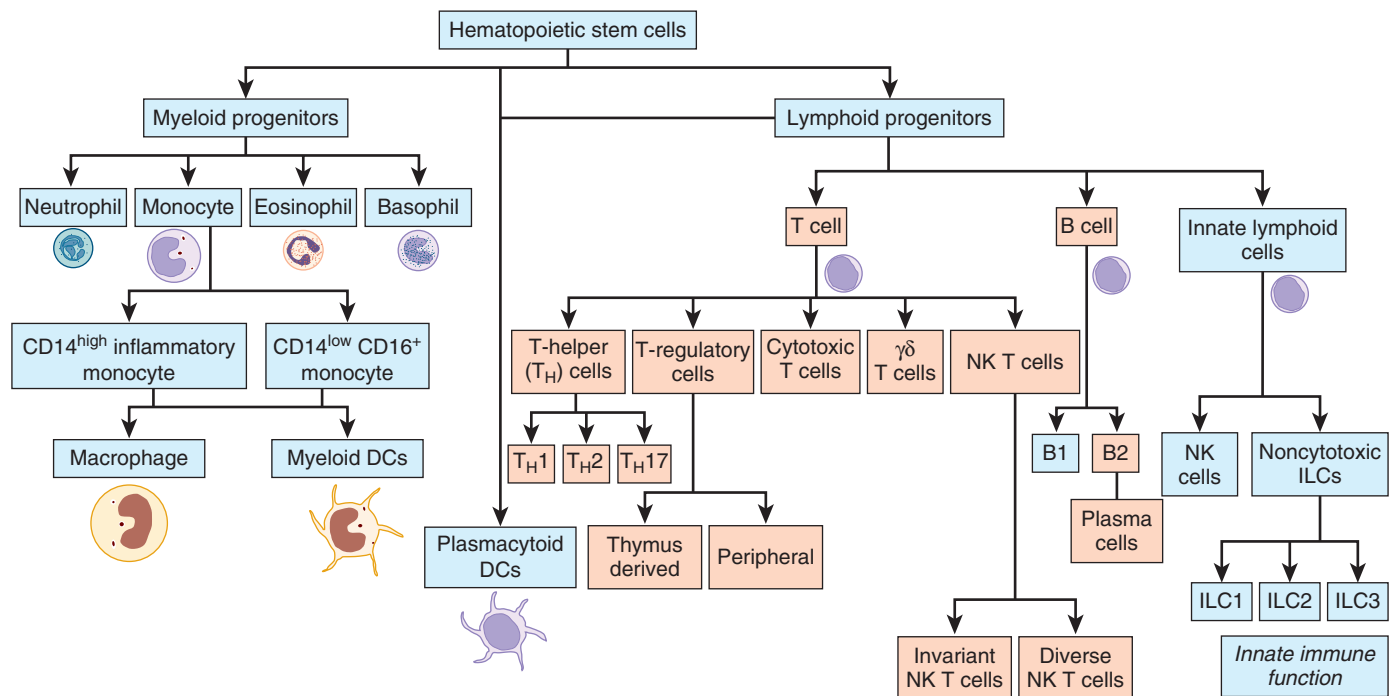

Circulating and Marginated Blood Neutrophil Pools

Circulating neutrophils are distributed into two compartments of approximately equal size, the circulating and marginated pools. As the name suggests, neutrophils in the circulating compartment freely circulate in the bloodstream, whereas those in the marginated compartment are transiently attached to the endothelium. In healthy adults, the circulating and marginated pools both contain approximately 0.4×10^7 cells per kilogram (Bishop et al., 1968). The marginated cells can move into the circulation for short periods of 30 to 45 minutes after strenuous crying or exercise or following administration of epinephrine or corticosteroids (Steel et al., 1971; Christensen and Rothstein, 1979).

Neutrophils remain in the circulation for a few hours (half-life of about 6.3 hours) and then migrate into the tissues. During infection, neutrophil trafficking into the tissues is increased. In fetal sheep, intra-amniotic exposure to endotoxin caused an initial drop in circulating neutrophil counts due to tissue emigration, which was followed by a gradual increase over the next 6 days. The length of time that neutrophils spend in the tissues and their subsequent fate are not well understood.

Neutrophil Heterogeneity

There is now evidence for the existence of different neutrophil subsets with distinct molecular markers. Details of differences in function are still emerging. Three molecular markers are highlighted next:

• **Fig. 83.1** Leukocyte Populations in the Neonate and the Young Infant. Hematopoietic stem cells differentiate along the myeloid and lymphoid lineages to ultimately give rise to leukocyte populations that participate in the innate (blue background) or adaptive (orange background) immune responses. DCs, Dendritic cells; ILC, innate lymphoid cell; NK, natural killer.

- Olfactomedin 4 (OLFM4) is a glycoprotein that has been suggested to act as a tumor suppressor and has recently been identified in specific granules of approximately 25% of circulating human neutrophils. Expression of OLFM4 could negatively regulate the efficiency of bacterial killing in a subset of neutrophils (Clemmensen et al., 2012).
- The surface glycoprotein CD177 (NB1) is a 55-kDa glycosylphosphatidylinositol-anchored receptor that is expressed at various levels on circulating neutrophils. Several distinct functions have recently been attributed to CD177, including high-affinity binding to platelet–endothelial cell adhesion molecule 1 and the ability to associate with the serine protease PR3. During infection, CD177⁺ neutrophil subsets may show increased tissue infiltration as aided by the associated cell surface PR3 (Hu et al., 2009).
- Interleukin-1 (IL-1)-positive neutrophils are believed to undergo reverse transendothelial migration from the tissues to enter the bloodstream and may be involved in the systemic dissemination of inflammation (Buckley, 2006).

Neonatal Neutropenia

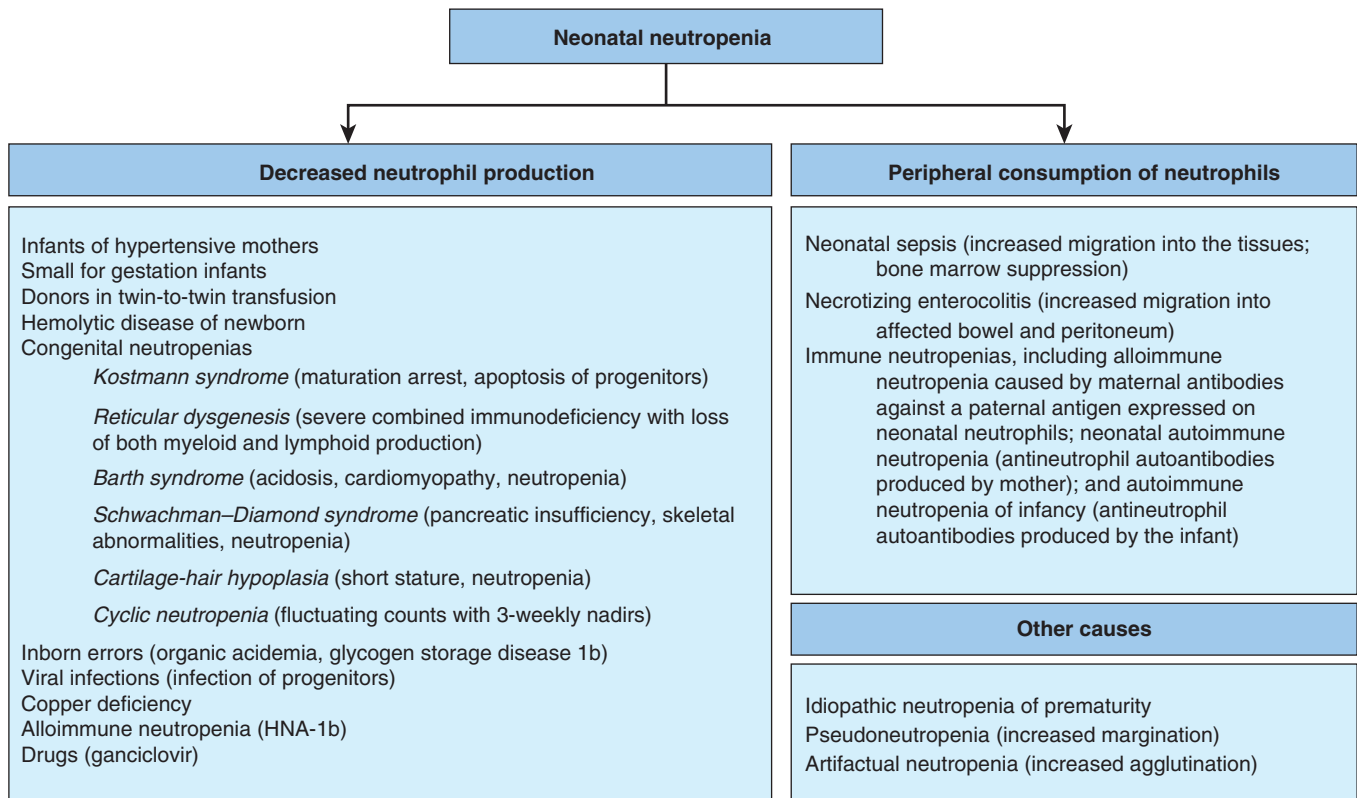

Statistically, neutropenia is defined as an absolute neutrophil count (ANC) less than two standard deviations below the mean value or below the fifth percentile for postnatal age. Manroe et al. (1979) established reference values for ANCs in term and preterm infants during the first 28 days of life for both healthy infants and those with perinatal complications. Mouzinho et al. (1994) studied serial white blood cell counts in healthy preterm very low-birthweight (VLBW) infants to investigate whether this patient cohort had neutrophil counts different from those found in previous studies

in which cohorts consisted mostly of term infants. They detected a wider range of the ANC, mostly resulting from a downward shift of the lower boundary, especially during the first 60 hours of life. However, there was no difference in absolute total immature neutrophil counts or in the ratio of immature neutrophil counts to total neutrophil counts. Schmutz et al. (2008) showed that the ANC peaked at 6–8 hours for neonates born at 28 weeks' gestation or later but at 24 hours for those born before 28 weeks' gestation. The 5th and 95th percentiles for ANCs at 72–240 hours among neonates born at more than 36 weeks' gestation were 2700/μL and 13,000/μL, respectively; for neonates born at 28 to 36 weeks' gestation they were 1000/μL and 12,500/μL respectively; and for neonates born at less than 28 weeks' gestation they were 1300/μL and 15,300/μL respectively. In that study, ANCs were higher in neonates born after a prolonged period of labor than in those born by elective cesarean delivery. Female infants also had higher ANCs, averaging about 2000/μL more than their male counterparts.

In neutropenic infants the pathophysiologic mechanisms include exhaustion of myeloid progenitors, inadequate response of the progenitor cells to proliferative or maturational signals, and increased usage and destruction. Fig. 83.2 highlights the causes of neutropenia in the newborn period. Some of the more frequently encountered causes of neonatal neutropenia are discussed in the following sections.

Sepsis-Induced Neutropenia

Neonates with overwhelming sepsis often develop neutropenia, which illustrates some of the differences between adult and neonatal neutrophils. Neonates have fewer neutrophil progenitors and a diminished precursor storage pool, so neutrophils are easily depleted in stress conditions (Levy, 2007). Following experimental sepsis

• **Fig. 83.2** Causes of Neonatal Neutropenia. HNA, Human neutrophil antigen.

with group B streptococci, adult rats respond with a transient decrease in circulating neutrophil counts, followed by significant neutrophilia associated with a twofold to threefold increase in the progenitor pool (colony-forming unit–megakaryocyte) and an increase in the proliferative rate to 75% of the maximal capacity (Christensen et al., 1982, 1983). In contrast, neonatal rats under the same conditions had a decrease of 50% of their progenitor pool and failed to increase their myeloid proliferative rate, which, as discussed previously, was already at near maximal levels. Most important, during experimental sepsis, neonatal rats had further depletion of their already reduced NSP reserves by almost 80%, compared with a decline of 33% in adult rats.

Alloimmune Neonatal Neutropenia

Alloimmune neonatal neutropenia occurs as a result of maternal sensitization to neutrophil antigens present on the infant's neutrophils (paternally acquired) that are not present on the maternal neutrophils, with subsequent production of immunoglobulin G (IgG). Neutrophil-specific antibodies are found in the maternal and infant sera, but the mother has a normal neutrophil count. Alloimmune neonatal neutropenia is estimated to occur at a frequency of 3% of live births (Curnette, 1993). The antigens most commonly involved in the United States are HNA-1a, HNA-1b, and Human Neutrophil Antigen (HNA)-2a. Because the antibodies are IgG, which crosses the placenta, peripheral blood counts show profound neutropenia. The condition is self-limiting and typically resolves within 6 to 7 weeks, during which time the neonate is susceptible to infections, mostly cutaneous in nature. Most infections are mild, although infants with profound neutropenia are at risk of life-threatening infections and should be monitored closely (Maheshwari et al., 2002a).

Maternal Hypertension–Associated Neutropenia

One of the most common and well-described causes of transient neonatal neutropenia is maternal hypertension. Neonatal neutropenia is inversely related to the birthweight and gestational age and directly related to the severity of the hypertension. Infants of hypertensive mothers seem to have decreased production of neutrophils, but the cause is uncertain. Several studies have demonstrated a decrease in the numbers of neutrophil progenitor cells, decreased cycling of these cells, a relatively normal NPP and NSP, and the absence of a “left shift” (Koenig and Christensen, 1989). Studies show conflicting evidence for the risk of infection in these infants (Doron et al., 1994; Mouzinho et al., 1994; Paul et al., 1999), although the risk is probably low because neutropenia resolves in most cases within 72 hours, and almost always in 5 to 7 days (Koenig and Christensen, 1991; Tsao et al., 1999).

Treatment of Neonatal Neutropenia

Recombinant granulocyte colony-stimulating factor (G-CSF) and granulocyte–macrophage colony-stimulating factor (GM-CSF) are often used to treat neonatal neutropenia. G-CSF stimulates neutrophil production, maturation, and release from the marrow and also reduces neutrophil apoptosis (Calhoun and Christensen, 2000). GM-CSF generates both granulocyte and macrophage colonies from precursor cells (Burgess and Metcalf, 1980). G-CSF is the primary systemic regulator of the circulating neutrophil concentrations (Calhoun and Christensen, 2000). GM-CSF may not play a major role in the steady state but is induced in inflamed tissues (Hamilton and Anderson, 2004).

Recombinant G-CSF or GM-CSF has been used in neonatal sepsis with conflicting results (Gillan et al., 1994; Schibler et al., 1998; Bedford Russell et al., 2001). In a meta-analysis of five

studies, G-CSF was shown to reduce mortality (odds ratio 0.17, 95% confidence interval [CI] 0.03–0.70) (Bernstein et al., 2001). However, this protective effect was no longer significant when nonrandomized studies were excluded. The role of GM-CSF in prevention or treatment of neonatal sepsis is also unclear (Cairo et al., 1999; Carr et al., 1999; Bilgin et al., 2001). Carr et al. (2003) reviewed the efficacy and safety of G-CSF/GM-CSF in the treatment or prophylaxis of neonatal sepsis. In preterm infants with suspected sepsis, G-CSF or GM-CSF did not reduce mortality at 14 days after the start of therapy (relative risk [RR] of death 0.71, 95% CI 0.38–1.33). However, in a subgroup of 97 infants with sepsis and neutropenia (ANC <1700/ μ L), there was a significant reduction in mortality (RR 0.34, 95% CI 0.12–0.92; number needed to treat 6, 95% CI 3–33).

Recombinant G-CSF is highly effective in correcting immune-mediated neutropenia. Along with its effects on neutrophil production, G-CSF may decrease antigen expression on neutrophils, rendering them less vulnerable to circulating antibodies (Rodwell et al., 1996), and also improve neutrophil function (de Haas et al., 1994). Similarly, G-CSF is also effective in many patients with congenital neutropenias (Christensen and Calhoun, 2004; Zeidler, 2005). Kostmann syndrome presents in early infancy with low ANC, often less than 200/ μ L, and recurrent bacterial infections. These patients have mutations in the neutrophil elastase gene *ELANE* (Dale et al., 2000). G-CSF can reduce the need for antibiotics and hospitalization (Zeidler, 2005) and can improve survival in these patients. Cyclic neutropenia is another rare hematologic disorder that may be modified by the use of G-CSF. Cyclic neutropenia is characterized by regular drops in ANC to levels as low as 250/ μ L at 3-week intervals (Dale and Hammond, 1988). Although the marrow may look normal during periods of higher ANC, it shows a characteristic “maturation arrest” of myeloid cells during or just before the onset of severe neutropenia. G-CSF treatment can be used to raise neutrophil counts during periods of severe neutropenia (Schmitz et al., 1995). These patients may not respond to GM-CSF (Schmitz et al., 1996).

Some premature infants can show idiopathic neutropenia that can be severe (sometimes ANC <500/ μ L) and prolonged but resolves spontaneously (La Gamma et al., 1995). These infants may be neutropenic at or shortly after delivery and can remain neutropenic for several weeks. Blood and bone marrow studies indicate decreased neutrophil production, although the cause remains unclear. In one study, G-CSF treatment induced a rapid rise in ANC in such patients, indicating that the marrow contains an adequate neutrophil reserve (Juul and Christensen, 2003).

G-CSF is administered intravenously or subcutaneously at a dosage of 5–10 μ g/kg per day. The response to G-CSF therapy and a rise in ANC usually occurs within 24–48 hours. In an occasional patient, G-CSF therapy will not raise blood neutrophil counts. In such a patient, G-CSF doses can be increased in increments of 10 μ g/kg at 7- to 14-day intervals if the ANC remains below 1000/ μ L (Zeidler et al., 2000; Maheshwari et al., 2002b). Doses can be reduced or withheld once the ANC exceeds 5000/ μ L. G-CSF treatment is usually tolerated in neonates without adverse effects. Long-term G-CSF therapy in congenital neutropenias has been associated with splenomegaly, thrombocytopenia, osteoporosis, myelodysplastic syndrome/leukemia, and development of anti-G-CSF antibodies (Taniguchi et al., 1993; Yakisan et al., 1997).

Intravenous immunoglobulin (IVIG) is effective in about 50% of infants with alloimmune and autoimmune neutropenia (Huizinga et al., 1990; Cartron et al., 1991; Yoshida et al., 1991). IVIG can mobilize neutrophils from the NSP, although repeated doses may

be needed for a sustained effect (Bussel et al., 1988; Christensen et al., 1991). While steroids are generally not effective in alloimmune neutropenia (Buckwold and Emson, 1959; Lalezari, 1984), they may raise the ANC for short periods in autoimmune neutropenia of infancy. Exchange transfusions are generally not effective in immune-mediated neutropenia (Hinkel et al., 1986).

Monocyte Physiology and Dysfunction

Ontogeny

Embryonic macrophages are found among hematopoietic cells in the yolk sac at 3–6 weeks' gestation. The fetal liver becomes the primary site of hematopoiesis from 6 weeks until midgestation, and the bone marrow then becomes the lifelong center of blood cell production (Palis and Yoder, 2001). Monocytes are present in high proportions in the early hematopoietic tissues, with approximately 70% of hematopoietic cells at 4.5 weeks' gestation morphologically identifiable as monocytes. This proportion falls to 1%–2% during the next 6 weeks as erythroid cells become predominant. The precursors of monocytes, monoblasts, and promonocytes continue to be present in the fetal liver; however, intravascular monocytes are not observed until the fifth month of gestation. Circulating monocytes do not appear with regularity until hematopoiesis is first established in the bone marrow after the 10th week of gestation.

During ontogeny, macrophages in the fetal liver express CD11b as early as 12 weeks' gestation. The classic monocyte marker, CD14, does not appear until about 15–21 weeks' gestation. CD14 expression on circulating mononuclear cells is equivalent in cord blood and adult peripheral blood. CD11a, CD11b, and CD11c are expressed in lower densities on cord blood monocytes than on adult cells. There is also lower expression of class II major histocompatibility complex (MHC) antigens HLA-DR, HLA-DP, and HLA-DQ on neonatal monocytes compared with adult monocytes. The density of these class II MHC antigens has been correlated with antigen-presenting capacity of monocytes in vitro, although the effect of this deficiency on neonatal host defense is not clear. Other important monocyte markers are the receptors for the Fc moiety of IgG (Fc γ R) and the Toll-like receptors (TLRs). Fc γ R receptors are important in the process of monocyte and macrophage phagocytosis of microbes and antibody-dependent cytotoxicity. Monocytes constitutively express the high-affinity receptor Fc γ RI (CD64) and Fc γ RII (CD32). TLRs play a critical role in the recognition of microbial pathogens. Term neonatal monocytes express normal basal levels of TLR2 and TLR4 but show reduced tumor necrosis factor (TNF) release in response to stimulation with a range of TLR agonists (Levy, 2005; Viemann et al., 2005; Sadeghi et al., 2007). Cord blood monocytes of preterm neonates, however, have lower TLR4 expression than adult peripheral blood monocytes (Forster-Waldl et al., 2005).

Macrophage colony-stimulating factor (M-CSF) is a hematopoietic growth factor that regulates the proliferation, differentiation, and functional activation of monocytes. Normally detected in human serum, M-CSF plays an important role in enhancing the effector functions of monocytes and macrophages. Serum M-CSF levels are increased in cord blood and rise further during the neonatal period.

Circulating Monocytes

Term infants show a relative monocytosis that persists through the neonatal period. Although there is some disagreement about normal

blood monocyte counts in neonates, we have described normal ranges of absolute monocyte counts (AMCs) using data from more than 62,000 blood counts (Christensen et al., 2010). In this cohort, blood monocyte concentrations increased almost linearly between 22 and 42 weeks' gestation. Monocyte concentrations also increased during the first 2 weeks postnatally. These data are consistent with previous kinetic studies in human fetuses that show a similar maturational increase in the concentrations of monocyte precursors (Linch et al., 1982; Porcellini et al., 1983). In neonates, monocytosis has been associated with prematurity, blood transfusions, albumin infusions, and theophylline therapy. Monocytosis has also been described in infants with congenital infections such as candidiasis and syphilis (Karayalcin et al., 1977; Wolach et al., 1991), and in association with immune-mediated neutropenia (Bux et al., 1991). In contrast, monocytopenia is not seen frequently in neonates, except in growth-restricted preterm infants who may have low monocyte counts as part of an overall suppression of all leukocyte lineages (Wirbelauer et al., 2010). Recently, we showed that a fall in AMCs can be a useful diagnostic marker of necrotizing enterocolitis (NEC) in VLBW infants (Remon et al., 2014). In this study, we compared blood counts obtained at onset of feeding intolerance with the last available counts obtained before the onset of symptoms. In a given infant with feeding intolerance, a drop in AMC of more than 20% indicated NEC with sensitivity of 0.70 (95% CI 0.57–0.81) and specificity of 0.71 (95% CI 0.64–0.77). The negative predictive value was 88%, indicating that the test may be valuable for exclusion of the diagnosis of NEC in infants with feeding intolerance due to other causes. Despite modest diagnostic accuracy, AMC is a convenient tool because the information is already available at no extra cost in complete blood counts from automated hematology analyzers.

Monocyte Subsets

Increasing evidence indicates that peripheral blood monocytes are a heterogeneous population comprised of “classic” CD14⁺CD16[−] monocytes, which express C-C chemokine receptor (CCR)2, CD64, CD62L and represent nearly 80%–90% of all blood monocytes. The remaining fraction comprises the “nonclassic” CD14^{low}CD16⁺ monocytes that lack CCR2 (Geissmann et al., 2003). Both subsets express the receptor for fractalkine, CX3C chemokine receptor (CX₃CR)1, but CD14^{low}CD16⁺ monocytes characteristically express higher levels. CD16⁺ monocytes are composed of at least two populations with strikingly distinct functions. Monocytes that express CD16 and CD14 (CD14⁺CD16⁺) also express the Fcγ receptors CD64 and CD32, have phagocytic activity, and produce TNF and interleukin (IL)-1β in response to lipopolysaccharide (LPS). In contrast, monocytes that express CD16 but very low levels of CD14 (CD14^{dim}CD16⁺) lack the expression of other Fc receptors, are poorly phagocytic, and do not produce TNF or IL-1β in response to LPS (Grage-Griebenow et al., 2001). This subset of “resident” monocytes patrol blood vessels in the steady state and extravasate during infection with *Listeria monocytogenes* or during tissue healing (Geissmann et al., 2008).

Function

Monocytes are capable of directed movement (chemotaxis) in response to chemoattractants produced by bacteria or by host cells at the site of injury or invasion. The chemotactic capabilities of neonatal and adult peripheral blood monocytes have been compared, and chemotaxis was found to be less pronounced in neonates than in adults (Table 83.1).

TABLE 83.1 Function and Phenotype of Adult Versus Neonatal Mononuclear Cells

| Cells | Function/Phenotype | Adult | Neonate |
|----------------------|-----------------------------|-------|---------|
| Monocytes | Chemotaxis | ↑ | ↓ |
| | Phagocytosis | ↑ | ↓ |
| | Adhesion | ≈ | ≈ |
| | Respiratory burst | ≈ | ≈ |
| Dendritic cells | Expression of CD83, CD86 | ↑ | ↓ |
| | Mixed lymphocyte reaction | ↑ | ↓ |
| | IL-12 (p40) production | ↑ | ↓ |
| | IL-12 production | ↑ | ↓ |
| | IL-10 production | ↓ | ↑ |
| Natural killer cells | Expression of CD8, CD57 | ↑ | ↓ |
| | Expression of ICAM-1, CD161 | ↑ | ↓ |
| | Cytolytic activity | ↑ | ↓ |

ICAM-1, Intercellular adhesion molecule1; IL, interleukin.

During an acute infection, circulating monocytes become activated and migrate into the tissues. During this process, monocytes adhere to the endothelium through the interaction of the integrins (CD11a, CD11b, CD11c, and CD18) expressed on the monocyte cell membrane, with ICAM-1 or ICAM-2 on the endothelial surface. Finally, the activated monocyte moves through the endothelium to the site of inflammation or infection. Preliminary studies demonstrate that the levels of monocyte adhesion molecule expression are comparable in neonate and adult peripheral blood (Schibler, 2000). The CD11b–CD18 complex (macrophage 1 antigen/complement receptor 3) promotes monocyte trafficking to the sites of infection by binding ICAM-1 and is also involved in the recognition of opsonized microbial pathogens.

Antimicrobial activity of monocytes includes oxygen-dependent mechanisms such as the respiratory burst, which through a complex series of reactions forms highly reactive hydroxyl radicals that damage host and microbial membranes. The ability of fetal and neonatal monocytes to kill pathogens (*Staphylococcus aureus*, *Staphylococcus epidermidis*, *Escherichia coli*, and *Candida albicans*) is generally comparable to that of the monocytes in adult peripheral blood (Table 83.1), although isolated preterm monocytes may show weaker superoxide production and degranulation in vitro than monocytes from term neonates.

On exposure to microbial antigens, monocytes and macrophages become activated by collaborative actions of soluble recognition proteins, including CD14 and TLRs, and produce several cytokines and chemokines contributing to the inflammatory process. IL-1β, interferon (IFN)-α, and TNF are synthesized at similar levels in adults and neonates. Kaufman et al. (1999) detected lower TNF production in LPS-stimulated adherent monocytes from preterm infants compared with monocytes from term infants; however, no difference was seen in the production of IL-1β or IL-6. They also found lower expression of CD11b and CD18 adhesion receptor subunits in preterm monocytes. Although TLR expression of term neonatal monocytes is similar to that of adult monocytes, there are important functional differences. Levy et al. (2004) reported that cord blood monocytes are less sensitive to TLR ligands than adult monocytes for TNF induction. The innate immune responses of neonatal monocytes to TLR agonists may be biased toward high

IL-6 levels but low TNF levels in vitro because of distinct neonatal cellular (monocyte) and humoral (serum) factors, and such a pattern was also evident in vivo (Angelone et al., 2006).

Developmental Defects in the Phagocytic Immune System in Neonates

The immaturity of the phagocytic immune system predisposes neonates to increased morbidity and mortality during bacterial sepsis. This impairment is attributed to developmental deficiencies in both the innate immune system and the adaptive immune systems (see Fig. 83.1). In the following section, we use the term *phagocyte* to refer mainly to neutrophils and the monocyte/macrophage lineage. Although immature DCs also show phagocytic activity, there is limited information about these cells in the neonate. To function efficiently the phagocyte system depends on the presence of adequate numbers of phagocytes in circulation, the ability to respond to signals from the sites of inflammation, the ability of phagocytes to migrate to these sites, and the capability of phagocytes to ingest and kill invading microorganisms.

Several studies show important differences in TLR expression on neonatal versus adult leukocytes. The basal expression of TLR2 and TLR4 in neutrophils and monocytes from healthy adults and term neonates is similar (Levy, 2007). During sepsis, neonates showed a sustained upregulation of TLR2 on monocytes but not on neutrophils, and there was no change in TLR4 expression on monocytes or neutrophils (Viemann et al., 2005). In VLBW infants, monocytes express TLR4 at much lower levels than in mature infants and adults and show significantly lower LPS-stimulated IL-1 β , IL-6, and TNF release in vitro (Forster-Waldl et al., 2005). Other studies have shown that stimulation of newborn monocytes with LPS produced a significant decrease in the expression of MyD88, supporting the premise of impaired TLR4-mediated signaling (Marodi, 2006). Belderbos et al. (2009) compared TLR-induced cytokine responses of whole blood leukocytes from cord blood from healthy term neonates, neonatal venous blood at the age of 1 month, and adult venous blood. On TLR4 activation, neonatal leukocytes (both at birth and at 1 month of age) showed a skewed pattern of cytokine expression, with low levels of T-helper (T_H) type 1–polarizing cytokines such as IL12p70 and IFN- α , and more of the antiinflammatory cytokine IL-10. In contrast, cytokine responses to TLR3, TLR7, and TLR9 matured by 1 month of age.

The immaturity of neonatal host defense is also characterized by profound deficiencies in quantitative and qualitative phagocytic effector cell function, particularly during stress or bacterial sepsis. The initial step in mounting a host defense response is directed migration, or chemotaxis (*chemo* refers to a chemical substance, *taxis* refers to rearrangement) of activated phagocytes toward the site of microbial invasion. Such movement occurs along concentration gradients of chemoattractants, which may include bacterial products such as *N*-formyl-L-methionyl-L-leucylphenylalanine (f-MLP), leukotriene B₄, complement products such as C5a, or chemokines. At the site of inflammation, the phagocytes ingest and kill the pathogens by oxygen-dependent and oxygen-independent mechanisms. Neutrophils from both preterm and term neonates show numerous qualitative abnormalities, including decreased deformability and impaired functions, including chemotaxis, phagocytosis, adherence, bacterial killing, aggregation, and oxidative metabolism. In contrast to neutrophils, neonatal monocytes are more comparable in function to the monocytes from adults.

GM-CSF increases adult neutrophil oxidative metabolism by augmenting superoxide anion production. Additionally, GM-CSF increases chemotaxis, promotes phagocytosis of *Staphylococcus aureus*, and augments neutrophil aggregation by the increased expression of surface adhesion molecules (Gasson et al., 1984; Weisbart et al., 1985). GM-CSF is not a direct stimulant of neonatal neutrophil function, but cord blood leukocytes show increased superoxide production if primed with GM-CSF before exposure to f-MLP or opsonized zymosan particles (Cairo et al., 1989).

The diminished inflammatory response of neonatal neutrophils results in a high incidence of microbial invasion. Significant defects in the upregulation of surface-active glycoprotein receptors (C3bi) and reduced aggregation also predispose the neonate to impaired response to bacterial infection. C3bi expression has been compared in adult and neonatal neutrophils and was found to be significantly less in neonatal neutrophils when stimulated by f-MLP– or zymosan-activated serum. However, cord blood neutrophils incubated with GM-CSF demonstrated a significant induction of C3bi expression. Also, a significant increase in C3bi expression was seen when cord blood neutrophils were pretreated with GM-CSF and subsequently stimulated with the calcium ionophore A23187. The upregulation of C3bi receptor by GM-CSF also appears to correlate with enhancement of neutrophil aggregation. GM-CSF also primes neutrophils for increased neutrophil aggregation following agonist (f-MLP) stimulation.

G-CSF and TNF have also been reported to modulate the function of adult and neonatal neutrophils in a manner similar to that for GM-CSF. Priming cord blood neutrophils with G-CSF or TNF and subsequent stimulation with f-MLP induces the expression of C3bi receptors and enhances bacterial and phagocytic activity and superoxide generation.

Leukocytes Contributing to Acquired Immunity

Lymphocytes form critical components of the acquired immune system and constitute 20% of blood leukocytes. There are two broad categories: (1) T lymphocytes, which mature in the thymus and subsequently seed peripheral lymphatic organs, including the spleen and lymph nodes, and (2) B lymphocytes, which are produced in the bone marrow, mature in secondary lymphoid organs, and subsequently differentiate into antibody-secreting plasma cells. The following sections outline the development and function of T and B lymphocytes in the neonate.

T-Lymphocyte Physiology and Function

Ontogeny

T-cell precursors undergo initial differentiation and maturation in the thymus, an organ that arises from the third branchial arch at approximately 6 weeks' gestation (Vacchio et al., 2016). Hematopoietic stem cells destined to become T-cell precursors move to the thymus by 9 weeks' gestation, initially entering the subcapsular cortical areas, and then undergo a period of differentiation as they move from the cortex to the medulla of the thymus. Lymphoid progenitors entering the cortical area do not express the T-cell receptor (TCR) or the coreceptors CD4 and CD8 and are therefore referred to as *double-negative thymocytes*. These cells genetically rearrange α and β genes to generate a TCR with unique antigen specificity. In the next stage of differentiation, this newly rearranged TCR is expressed on the cell surface along with *both* CD4 and

CD8, and the cells are termed *double positive*. T cells with TCRs that recognize MHC bound to microbial peptides are “positively selected.” Following the double-positive stage, T cells lose expression of either CD4 or CD8 to become “single positive,” and during this stage, T cells that recognize “self-peptides” are negatively selected to undergo apoptosis. At the end of this differentiation process, mature T cells that enter the medulla are either CD4⁺ or CD8⁺ and can bind host MHC but only when it is not bound to self-antigens. Approximately 98% of thymocytes are eliminated during this process.

T-Cell Receptor Repertoire

The TCR is composed of two different protein chains that are associated with CD3, a protein involved in signal transduction. Most T cells carry a TCR composed of α and β chains, but in about 5% of all T cells, the TCR comprises γ and δ chains instead. Each TCR protein chain contains an immunoglobulin-like extracellular region with a variable (V) domain at its N-terminal and a constant (C) domain at the C-terminal end. The variable domains contain hypervariable, complementary-determining regions (CDRs). The third CDR (CDR3) imparts affinity for a specific processed antigen (Zemlin et al., 2002).

TCR diversity arises from genetic recombination of DNA encoding for variable (V), diversity (D), and joining (J) gene segments in individual T cells using recombination activating gene (RAG)1 and RAG2 recombinases or gene conversion using cytidine deaminases. These recombinations create a diverse pool of T cells with a wide repertoire of antigen specificity.

T-Cell Subtypes

T cells are broadly categorized as CD4⁺, CD8⁺, or T cells that are neither CD4⁺ nor CD8⁺. CD4⁺ T cells recognize antigens bound to class II MHC molecules and are further classified into T_h cells and T-regulatory cells, commonly referred to as T_{regs}.

T-Helper Cells

Naïve CD4⁺ cells differentiate into three distinct effector T_h subsets: T_h1, T_h2, and T_h17 (Zhu et al., 2010). T_h1 cells are inflammatory cells that interact with mononuclear phagocytes and provide cellular immunity against intracellular pathogens and virus-infected cells. These cells produce IL-2, IFN- γ , TNF, IL-13, and GM-CSF. T_h2 cells associate with B cells and defend against helminths and play a role in allergic reactions through regulation of antibody isotype switching. These cells produce IL-4, IL-5, IL-9, IL-10, IL-12, and IL-13 (Saito et al., 2010). T_h17 cells protect against infections, where they take on a T_h1-like effector function to promote pathogen clearance by enhancing neutrophil recruitment to sites of infection, and also by activating macrophages. These cells can also play a pathogenic role in allergic, autoimmune, and other chronic inflammatory diseases (Weaver et al., 2006; Ivanov et al., 2007; Cosmi et al., 2008). These cells produce cytokines such as IL-17A, IL-17F, IL-21, IL-22, and IL-26.

Regulatory T Cells

T_{regs} are derived from naïve T cells (Bluestone and Abbas, 2003). The transcriptional regulator forkhead box P3 (FoxP3) plays a critical role in the development of T_{regs} and is often used as a biomarker for these cells. T_{regs} downregulate the immune response by expressing inhibitory cytokines (IL-10, transforming growth factor β), cytotoxic molecules, modulators of cyclic AMP, and cytokine competition to limit effector and/or antigen-presenting cell function (Burt, 2013).

Two populations of T_{regs} have been identified: thymus-derived T_{regs} (tT_{regs}) and peripherally derived T_{regs} (pT_{regs}). tT_{regs} develop in the thymus, whereas pT_{regs} develop in the periphery from naïve T cells (Abbas et al., 2013). CD4⁺CD25⁺FoxP3⁺ T_{regs} are important contributors to the control of the immune response in the fetus/neonate. In the fetus, CD4⁺ T cells have a predisposition to differentiate into tolerogenic T_{regs} that promote self-tolerance. During midgestation, CD4⁺CD25⁺FoxP3⁺ T_{regs} may constitute 15%–20% of all CD4⁺ cells in the lymphoid tissues (Cupedo et al., 2005; Michaelsson et al., 2006). T_{regs} represent less than 5% of all CD4⁺ cells in cord blood from term infants and in the adult peripheral blood (Michaelsson et al., 2006).

Cytotoxic T Lymphocytes

Following antigen presentation and activation, CD8⁺ T cells can differentiate into cytotoxic T lymphocytes (CTLs). These cells protect against intracellular pathogens and also play a role in graft rejection and tumor surveillance (Gromo et al., 1987; Liu et al., 1996). CTLs cause cytotoxicity by releasing pore-forming mediators (perforin/granzyme system) or by activating the Fas/Fas ligand-dependent apoptotic pathway (Kagi et al., 1996; Smyth et al., 2001).

$\gamma\delta$ T Cells

$\gamma\delta$ T cells are detectable in the fetal thymus and liver at 6–8 weeks' gestation. At 16 weeks' gestation, $\gamma\delta$ T cells constitute 10% of circulating T cells but the proportion gradually declines to about 3% at term (McVay and Carding, 1996; Holtmeier et al., 2001). Postnatally, these cells are present mainly on skin and mucosal surfaces. Although the role of $\gamma\delta$ T cells remains unclear, these cells respond to nonpeptide microbial metabolites, show cytotoxicity, and produce cytokines such as IFN- γ and TNF (Hintz et al., 2001; Yamashita et al., 2003). The cytotoxicity of neonatal $\gamma\delta$ T cells is significantly less than that of their counterparts from adults (Morita et al., 1994).

Natural Killer T Cells

Natural killer (NK) T cells are a subset of T cells that express TCR $\alpha\beta$ chains as well as a variety of NK cell markers (Rhost et al., 2012; Kumar and Delovitch, 2014). These cells recognize both exogenous and endogenous lipid antigens in the context of the MHC-like molecule CD1d. CD1d-restricted NK T cells are classified into two main subsets: type I or invariant NK T cells and type II or diverse NK T cells. Type I NK T cells express a conserved $\alpha\beta$ TCR and constitute less than 1% of T cells in cord blood (Bendelac et al., 1997; Lopez et al., 2014). These cells have been identified in the human fetal small intestine (Loh et al., 2014). Type II NK T cells are more abundant than type I NK T cells in humans and express relatively diverse TCR α and β chains.

Circulating T Cells

Term neonates have higher counts of CD4⁺ T cells in peripheral blood than adults. The CD4/CD8 ratio is high (up to 4.9:1) in neonates and declines to adult values (2:1) by 4 years of age (Panaro et al., 1991; Erkeller-Yuksel et al., 1992). In cord blood, 85% of the T cells express CD38 (compared with less than 5% in adults) but lack other markers of activation (Wilson, 1991). Nearly 80% of all T cells in cord blood display a naïve CD45RA phenotype, compared with less than half of the circulating T cells in adults (Pirenne et al., 1992; Hassan and Reen, 1993). The proportion of memory CD45RO T cells reaches adult levels only by the second decade (Pirenne et al., 1992).

Neonatal T-Lymphocyte Function

T cells form a critical component of the adaptive immune defense system in the neonate. Although term infants have higher T-cell counts in peripheral blood than adults (Walker et al., 2011), preterm neonates tend to have lower CD4⁺ and CD8⁺ lymphocyte counts than their term counterparts. This deficiency could, at least in part, place the preterm infant at risk of infection. In contrast to the CD4⁺ effector T cells, preterm infants have more T_{regs} in cord blood than do term infants or than adults do in peripheral blood (Correa-Rocha et al., 2012).

Studies suggest altered function of CD4⁺ T cells in neonates compared with adults. T_H1 cell function is decreased in human neonates. Neonatal CD4⁺ T cells secrete less IL-12 and IFN- γ and express less CD154 (CD40 ligand) on their surface than their counterparts from adults (Chen et al., 2006). Cord blood lymphocytes also show limited capacity to produce IL-17 (Schaub et al., 2008). Similarly, both preterm and term neonatal T_{regs} appear less functional than their adult counterparts. T_{regs} from neonates limit contact between DCs and conventional T cells, downmodulating the expression of costimulatory molecules by DCs. This results in decreased DC immunogenicity and impaired T-cell activation (Rueda et al., 2015).

T-cell signals from antigen presentation and T-cell–derived cytokines such as IL-2, IL-4, IL-5, IL-6, IL-10, IL-13, and IFN- γ are required for B-cell proliferation, differentiation, and survival (Bishop and Hostager, 2001). T-cell and B-cell cross talk also involves receptor ligand pairs such as CD40 (on B cell)–CD40 ligand (on T cell), which is critical during B-cell immunoglobulin isotype switch, and B7–CD28, CD11a (lymphocyte function–associated antigen–1)–ICAM-1, and CD58–CD2 (Bishop and Hostager, 2001). Neonatal T cells show lower CD40 ligand expression than adults and are less efficient at providing humoral and CD40-dependent activation signals to B cells (Splawski et al., 1996; Nonoyama et al., 1998).

CTL function is also less efficient in the neonate compared with the adult (Toivanen et al., 1981). Neonatal CTLs express less perforin than their counterparts from adults. Circulating inhibitors, such as alpha fetoprotein and prostaglandins, have been implicated as the cause of impaired CTL activity in neonates (Lubens et al., 1982).

B-Lymphocyte Physiology and Function

Ontogeny

B-cell progenitors are derived from pluripotent hematopoietic cells in the bone marrow (Klein, 1983). The first recognizable B-cell progenitor is the large pre-B cell, which is characterized by the presence of cytoplasmic μ heavy chains. Pre-B cells can be identified in the fetal liver as early as 7 weeks' gestation and in the marrow by 12 weeks. Immature B cells undergo a selection process analogous to T cells to eliminate self-identifying clones (Nossal, 1986; Buhl et al., 2000). Once B cells begin to express surface IgM (sIgM), they are ready to leave the bone marrow to enter the peripheral circulation (Rudin and Thompson, 1998); sIgM⁺ B cells can be seen in the fetal liver by 9 weeks and in the bone marrow, peripheral blood, and spleen by 12 weeks. B cells with surface IgA, surface IgG, and surface IgD (sIgD) isotypes appear between 10 and 12 weeks (Gathings et al., 1977). IgM/IgD⁺ B cells populate the lymph nodes at 16 weeks. Plasma cells are first seen around 20 weeks' gestation. By 22 weeks, the proportion of B cells in the spleen, peripheral blood, and marrow is similar to that in adults (Gathings et al., 1977; Bofill et al., 1985). The bone marrow

becomes the exclusive site for B-cell maturation by 30 weeks' gestation.

B-Cell Subtypes

In the fetus and neonate, most B cells express CD5, a T-cell antigen, on the cell surface. These CD5⁺ B cells have been referred to as *B1 cells* to differentiate them from the conventional B2 cells seen in adults. These B1 cells show greater capacity for bone marrow–independent self-renewal, display an unusual CD11b⁺ sIgM^{high} sIgD^{low} phenotype, and show constitutive expression of the transcription factor signal transducer and activator of transcription 3 (Hardy and Hayakawa, 1994; Karras et al., 1997). These cells are the predominant B-cell type during fetal life and show a distinctive anatomic localization in the spleen and the peritoneal cavity (Antin et al., 1986; Bhat et al., 1992). In adults, CD5 expression can be found on about 25%–35% of all B cells and on less than 5% of mononuclear cells in peripheral blood. In contrast, CD5⁺ B cells represent 90% of all B cells in cord blood. The proportion falls to 75%–80% during infancy and approaches adult levels only by late adolescence (Antin et al., 1986; Bhat et al., 1992).

The role of B1 cells in the fetus is still unclear. Their unique localization, their broad polyspecific specificities, and the restricted immunoglobulin repertoire suggests a role in innate immunity rather than in adaptive immunity (Hardy and Hayakawa, 1994). Unlike follicular B2 cells, which respond to protein antigens and show immunoglobulin heavy chain class switching and affinity maturation, B1 cells respond mainly to T-cell–independent carbohydrate antigens (Hardy, 2006; Dorshkind and Montecino-Rodriguez, 2007).

Circulating B Cells

Cord blood contains more B cells than adult peripheral blood, although the ratio of B cells to circulating T cells is similar (Paloczi, 1999). B-cell counts peak at 3–4 months and then decline gradually to adult levels by 6 years of age (Ugazio et al., 1974). Preterm infants have B-cell counts comparable to those of term infants, although the number may be smaller in growth-restricted infants (Thomas and Linch, 1983). Unlike adults, most B cells in cord blood express activation markers such as CD25, CD23, and transferrin receptor (Durandy et al., 1990).

Neonatal B-Lymphocyte Function

Immunoglobulin Production

The fetus and the neonate are capable of mounting an antibody response to antigenic challenges, although they may not be able to respond to all the antigens in a vaccine or may show other deficiencies such as a delayed isotype switch (D'Angio et al., 1995). Overall, postnatal age seems to be a better predictor of antibody response than the gestational age. Both preterm and term infants immunized with diphtheria toxoid in the first 10 days after birth showed weaker antibody responses than similarly immunized adults, but the response was more robust when the vaccine was administered at 1–2 months of age (D'Angio et al., 1995). Similarly, premature infants respond poorly to the hepatitis B vaccine in early infancy but show antibody responses comparable with those of their term counterparts in later infancy (Golebiowska et al., 1999).

Immunoglobulin Repertoire

Immunoglobulin diversity is generated by DNA recombination involving various V, D, or J gene segments, giving rise to a large number of V(D)J permutations (Oltz, 2001). Additional diversity

is generated by imprecise gene segment joins, addition of extra nucleotides to the splice junction of the VDJ joins, and somatic mutations (Kelsoe, 1999; Neuberger, 2005).

In the fetus and neonate, the immunoglobulin repertoire is relatively limited. During early gestation and midgestation, the heavy chain V (V_H) gene segments located closest to the J segments are utilized preferentially, resulting in shorter CDR3 regions than in adults. This altered architecture of the antigen-binding site has been postulated to allow greater polyspecificity of antigen binding, although at a cost of lower antibody affinity (Schroeder et al., 1987; Casali and Schettino, 1996). The utilization of V_H segments spreads out more evenly with increasing gestation but does not reach adult levels (Choi et al., 1995). In general, the antibody response in neonates is of low affinity and restricted to the IgM isotype. Somatic mutation of the heavy and light immunoglobulin variable region genes and the selection of higher affinity antibody-producing B cells is also limited at birth and increases slowly after 10 days of age (Ridings et al., 1997).

Serum Immunoglobulin Levels

At birth, most of the Igs present in serum are derived from transplacental transfer of maternal IgG (particularly IgG1 and IgG3) during the third trimester (McNabb et al., 1976; Palfi et al., 1998). Serum IgG levels in term neonates (up to 1000 mg/dL) may be similar to or higher than those in maternal serum, although preterm infants, who did not receive the maternal antibody, have lower IgG levels (Kohler and Farr, 1966; Hobbs and Davis, 1967). During early infancy, Ig levels fall because of normal turnover to reach a nadir of 300–500 mg/dL at 3–5 months of age, when the infant starts producing increasing amounts of his or her own. This nadir is reached earlier and is typically lower in preterm infants (Ballow et al., 1986).

Dendritic Cell Physiology and Function

DCs are specialized mononuclear cells with highly developed antigen-presenting capabilities that play a pivotal role in humoral and cellular immunity by initiating T-cell responses. DCs have a distinct morphology and are noted for their irregular shape with veil-like ruffled cell membranes (lamellipodia), many pseudopods, and numerous membrane processes. Microscopic examination of DCs reveals prominent mitochondria, endosomes, and lysosomes within the cytoplasm, which are necessary for the processing of antigen. The morphology of DCs in cord blood and adult peripheral blood is identical, although cord blood contains a lower proportion of DCs (0.5%) than adult blood (1%).

Ontogeny

Most DCs are derived from pluripotent hematopoietic stem cells differentiating along myeloid or lymphoid lineages. An exception may be the *follicular DCs*, a nonmigratory population of DCs located in the paracortical areas of the spleen and lymph nodes, which may be of mesenchymal origin (Kapasi et al., 1998).

Dendritic Cell Subtypes

In humans, DCs are usually classified into the following subsets (Ziegler-Heitbrock et al., 2010):

1. *Myeloid DCs (mDCs)* express typical myeloid antigens CD11c, CD13, CD33, and CD11b and are homologous to mouse CD11c⁺ “classic” or “conventional” DCs. In humans, mDCs

may be split into CD1c⁺ and CD141⁺ fractions (Jongbloed et al., 2010; Mittag et al., 2011). CD1c⁺ mDCs are the major population of human mDCs in blood (1% of mononuclear cells), tissues, and lymphoid organs. In lymph nodes, CD1c⁺ DCs are found as “interdigitating cells” of T-cell areas. The expression of CD141 (thrombomodulin) is seen on approximately 10% of human blood mDCs (0.1% of mononuclear cells). These cells show enhanced ability to take up necrotic cells, sense viral nucleic acids with TLR3 and TLR8, and cross-present antigen to CD8⁺ T cells (Jongbloed et al., 2010).

2. *Plasmacytoid DCs (pDCs)* typically lack myeloid antigens and are distinguished by expression of CD123 (IL-3 receptor), CD303 (C-type lectin domain family 4, member C), and CD304 (neurophilin). These cells are not related to plasma cells; the name reflects subtle lymphoid features and abundant secretory properties. In quiescent tissues, there are few pDCs, but they may constitute up to 20% of MHC class II–positive cells in lymph nodes and are rapidly recruited to both sites during inflammation. Further, pDCs express high levels of TLR7 and TLR9 and release type 1 IFN in response to viruses (Liu and Nussenzweig, 2010).
3. *CD14⁺ DCs* are a third subset of CD11c⁺ DCs found in tissues and lymph nodes. Originally described as “interstitial DCs,” these cells are more monocyte-like than the other mDCs and may arise from classic CD14⁺ monocytes (Haniiffa et al., 2012).
4. *Langerhans cells and microglia* are two specialized self-renewing DC populations found in stratified squamous epithelium and the brain parenchyma, respectively.

DC populations in blood include pDCs and CD1c⁺ and CD141⁺ mDCs; these cells are immature forms of those found in tissues and lymph nodes. Most epithelial tissues contain “migratory” DC populations that acquire antigen and migrate via the afferent lymphatics to lymph nodes, where they present antigens to T cells. In the steady state, tissues contain CD1c⁺ mDCs, CD141⁺ mDCs, and CD14⁺ DCs but few pDCs. Lymphoid tissue contains blood-derived nonmigratory “lymphoid” or “resident” DCs and some migratory DCs from the tissues (Segura et al., 2012).

Mature DCs express high levels of CD80 and CD83 on the cell membrane. Several agents have been shown to increase CD80 and CD83 expression on DCs, including TNF, bacterial endotoxin, and monocyte-derived inflammatory signals. Interactions with other cells also can induce maturation of DCs, as demonstrated by T-cell–mediated cross-linking of CD40.

Morphology

DCs express numerous surface molecules commonly found on mononuclear cells, MHC molecules, CD4, CD45 isoforms, adhesion molecules (ICAM-1, ICAM-2, ICAM-3, and leukocyte function–associated antigen 1), and Fc receptors (FcγRI [CD64] and FcγRII [CD32]). Maturation of DCs is commonly associated with high expression of CD80 and CD83. On stimulation, DCs upregulate the costimulatory molecules CD40, CD80, and CD86. Cord blood DCs express lower levels of ICAM-1 (CD54), MHC class I (HLA-ABC) and MHC class II (HLA-DR), CD80, and CD40 antigens than DCs in adult peripheral blood (Goriely et al., 2001; Hunt et al., 1994). Liu et al. (2001) compared monocytes from cord blood and adult peripheral blood for the capacity to generate DCs; cord blood monocytes generated fewer DCs, which also showed lower MHC class II expression. The endocytotic ability and ability to stimulate CD3⁺ T cells were also reduced in cord blood DCs.

Function

The activation of TLR pathways has been shown to mediate DC maturation. Krutzik et al. (2005) demonstrated that TLR activation of monocytes induces rapid differentiation to DCs that could be expanded by TLR-mediated upregulation of GM-CSF. Cord blood monocyte-derived DCs showed lower expression of the maturation markers CD83 and CD86 and produce less IL-12 (p40, p70) than adult DCs (Goriely et al., 2001; Krumbiegel et al., 2007; Belderbos et al., 2009). In mixed leukocyte culture with adult CD4⁺ T cells, neonatal DCs induced significantly lower levels of IFN- γ but higher levels of IL-10 than did adult DCs (Table 83.1). Furthermore, neonatal DCs also performed poorly as accessory cells for T-cell mitogenic responses (Hunt et al., 1994).

Innate Lymphoid Cell Physiology and Function

Innate lymphoid cells (ILCs) include the classic cytotoxic NK cells and the recently described noncytotoxic ILC populations (Artis and Spits, 2015). These cells are characterized by a classic lymphoid cell morphology but, unlike the adaptive T and B cells, do not show antigen specificity and function as a part of the innate immune system.

Natural Killer Cell Physiology and Function

NK cells have the ability to lyse target cells and secrete immunomodulatory cytokines (Robertson and Ritz, 1990). These cells make up 10% of peripheral blood lymphocytes and are characterized by the lack of the lymphocyte marker CD3 but expression of CD56 (Farang et al., 2002).

Ontogeny

NK cells develop from the committed lymphoid progenitors in the aortogonadomesonephron and later within the fetal liver (Godin and Cumano, 2002). Lineage-specific NK-cell progenitors are first identified in the fetal thymus and later in the bone marrow (Miller et al., 1992; Shibuya et al., 1993; Carlyle and Zuniga-Pflucker, 1998). Human NK-cell development requires early growth factors such as fms-like tyrosine kinase (Flt)-3 ligand or Kit ligand and later IL-15.

Natural Killer Cell Subtypes

NK cells can be classified on the basis of the surface density of CD56 into CD56^{bright} NK cells and CD56^{dim} NK cells. Early NK cells are CD56^{bright}, which then undergo further differentiation into CD56^{dim} NK cells. The CD56^{dim} NK cells are the more cytotoxic of the two categories and represent 90% of the NK-cell population. These cells express CD16 (Fc γ RIII) and show antibody-dependent cellular cytotoxicity (Leibson, 1997).

Function

NK cells express a repertoire of classes of receptors that bind to MHC class I or MHC class I-like molecules that regulate whether NK cells will be activated or inhibited (Moretta et al., 2001; Farang et al., 2002). When NK cells fail to interact with the MHC class I molecules and the activating receptor is activated, NK-cell-mediated cell lysis will ensue, as occurs in the case of infection (Moretta et al., 2005). After activation, lysosome-like vesicles containing perforin, serine esterases, and sulfated proteoglycans

are secreted toward the target cell. Perforin forms pores in the target cell, leading to osmotic lysis. The serine esterases, including granzymes, induce apoptosis (Robertson and Ritz, 1990; Berthou et al., 1995; Spaeny-Dekking et al., 2000; Moretta et al., 2005; Pao et al., 2005). After stimulation with cytokines, CD56^{bright} NK cells produce positive feedback loops by secreting IFN- γ , TNF, and GM-CSF. These cytokines help to recruit macrophages and other antigen-presenting cells for more efficient control of the infection (Cooper, 2001a, 2001b).

Neonatal NK cells show functional immaturity, which leads to an impaired immune system. Cord blood NK cells show lower expression of CD8 and CD57, two markers associated with NK cell maturation (Dalle et al., 2005; Table 83.1). Cord blood NK cells also express less ICAM-1 and CD161, which are involved in endothelial adhesion and activation, respectively, than adult NK cells (Dalle et al., 2005). Neonatal NK cells also show less cytolytic activity compared with adult NK cells, which results in impaired clearance of intracellular pathogens (Dalle et al., 2005; Wynn et al., 2009).

Noncytotoxic Innate Lymphoid Cell Physiology and Function

Ontogeny

Similarly to NK cells, noncytotoxic ILCs are also derived from the common lymphoid progenitor that differentiates into precursors committed to the various subsets. Recent studies have confirmed that NK cells and noncytotoxic helper ILCs belong to distinct cell lineages (Constantinides et al., 2014; Klose et al., 2014).

Innate Lymphoid Cell Subtypes

Noncytotoxic ILCs are characterized by a classic lymphoid cell morphology, express IL-2 receptor α and IL-7 receptor α , but unlike the adaptive T and B cells, ILCs do not exhibit antigen specificity. There are three groups of noncytotoxic ILCs: group 1 ILCs (ILC1s), group 2 ILCs (ILC2s) and group 3 ILCs (ILC3s) including lymphoid tissue inducer (LTi) cells. These subsets are defined on the basis of differential requirements for transcription factors during development, expression of effector cytokines, and the acquisition of other distinct effector functions (Spits et al., 2013).

The three ILC subsets function in the absence of antigen specificity but exhibit remarkable functional similarity with the T_h cell subsets, T_h1, T_h2, and T_h17, respectively, in cytokine expression and effector function (Artis and Spits, 2015). ILC1s express the T-bet transcription factor and produce T_h1-associated cytokines such as IFN- γ and TNF to protect against intracellular bacteria and parasites. ILC2s express the transcription factor GATA-binding protein 3 and produce T_h2-associated cytokines (including IL-4, IL-5, IL-9, and IL-13) and/or the epidermal growth factor receptor ligand amphiregulin. These cells promote type 2 inflammation seen during tissue repair, allergic disorders, and antihelminth immunity. ILC3s express the transcription factor RAR-related orphan receptor γ T, have a cytokine signature similar to that of T_h17 cells, and produce IL-17A, IL-17F, IL-22, GM-CSF, and TNF, to promote antibacterial immunity, chronic inflammation, or tissue repair. ILC3s comprise two subsets that can be distinguished on the basis of their expression of the chemokine receptor CCR6. CCR6⁺ ILC3s encompass CD4⁺ and CD4⁻ LTi cells. The CCR6⁻ ILC3 population may be further categorized on the basis of the expression patterns of natural cytotoxicity receptors.

Function

There is limited information on ILCs in the fetus and neonate. ILC2 cells are detectable in cord blood and may be present in higher proportions in male neonates than in female neonates (Forsberg et al.; 2014). In a murine model of gastroschisis, organs exposed to amniotic fluid were shown to contain high numbers of ILC2 and ILC3 and eosinophilia, which was reversed by the administration of anti-IL5 antibody (Frascoli et al., 2016). In another study, ILC3s were implicated as a source of increased IL-17 levels seen in patients with preeclampsia, and

gestational/chronic diabetes was associated with ILC3s (Barnie et al., 2015).

ILC3s are abundant at mucosal surfaces, particularly in the gastrointestinal tract. There is evidence that the development and function of some subsets of ILC3s are induced in response to microbial colonization and are involved in enhancing B-cell IgA production (Magri et al., 2014). In addition, there is evidence that IL-22 production by ILCs plays an important role in containing and shaping the composition of the intestinal microbiota (Sonnenberg et al., 2011).

Summary

Immaturity of neonatal neutrophils, monocytes, lymphocytes, DCs, and ILCs predisposes newborns to an increased incidence and/or severity of infectious complications. An increased understanding

of the genetic mechanisms responsible for these defects will provide insight regarding future treatment strategies to prevent and/or treat serious or overwhelming infection in the newborn.

Neonatal Indirect Hyperbilirubinemia and Kernicterus

JON F. WATCHKO

KEY POINTS

- Early clinical jaundice or rapidly developing hyperbilirubinemia is often a sign of hemolysis, the differential diagnosis of which commonly includes immune-mediated disorders, red cell enzyme deficiencies, and red cell membrane defects.
- Knowledge of the maternal blood type and antibody screen is critical in identifying non-ABO alloantibodies in the maternal serum that may pose a risk for severe hemolytic disease of the newborn.
- Knowledge of the hour-specific predischARGE bilirubin measurement and the infant's gestational age in weeks is critical to determining appropriate timely post-birth hospitalization follow-up and evaluation.
- Hyperbilirubinemia in late-preterm neonates (34^{0/7}–36^{6/7} weeks' gestation) is more prevalent, more pronounced, and more protracted than in their term counterparts, and these immature neonates are more vulnerable to bilirubin-induced brain injury.
- Glucose-6-phosphate dehydrogenase (G6PD) deficiency is a noteworthy cause of bilirubin encephalopathy worldwide. Clinicians everywhere must have a high index of suspicion for G6PD deficiency in neonates whose genetic heritage derives from Africa, the Middle East, the Mediterranean region, and Asia.

Hyperbilirubinemia is the most common clinical condition requiring evaluation and treatment in the newborn and a frequent reason for hospital readmission during the first week of life. Although generally a benign, postnatal, transitional phenomenon, a few neonates develop marked potentially hazardous bilirubin levels that can pose a direct threat of serious brain injury (Watchko and Tiribelli, 2013). Acute bilirubin encephalopathy (ABE) may ensue and evolve into kernicterus (chronic bilirubin encephalopathy), a permanent disabling neurologic condition classically characterized by (1) the movement disorders of dystonia and/or choreoathetosis, (2) hearing loss caused by auditory neuropathy spectrum disorders, and (3) oculomotor pareses (Watchko and Tiribelli, 2013).

Total serum bilirubin (TSB) is the measure of albumin-bound bilirubin, whereas the small circulating fraction not bound to albumin or other serum proteins is indexed by the unbound or “free” (Bf) bilirubin level. There is a keen interest in circulating Bf, its measurement, and its ability to predict bilirubin-induced

neurologic injury. Indeed, Bf is the vehicle of bilirubin's biologic effects in the brain. However, bilirubin-induced neurotoxicity depends on a complex interaction between the level and duration of central nervous system (CNS) Bf exposure and the innate cellular characteristics of the developing CNS that may predispose or protect against bilirubin-induced neuronal injury, and the clinical laboratory measurement of circulating Bf is not generally available (Watchko and Tiribelli, 2013). As a result, clinicians must rely on the TSB and the bilirubin/albumin (B/A) ratio, an imperfect surrogate of circulating Bf, to index the risk for ABE and drive treatment decisions.

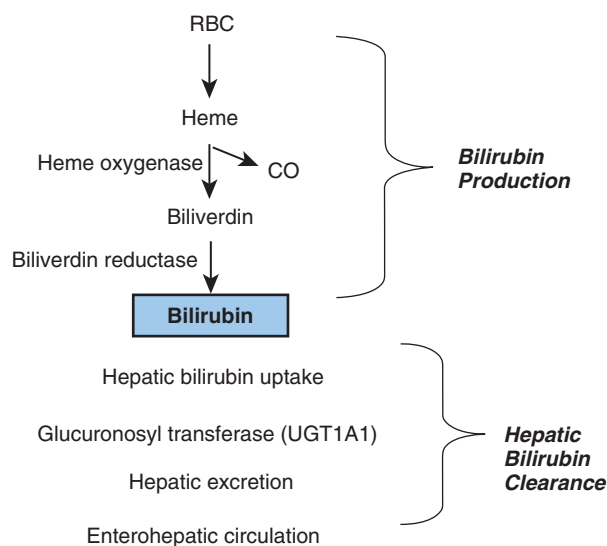

The genesis of neonatal hyperbilirubinemia reflects the interplay of developmental red blood cell (RBC), hepatic, and gastrointestinal immaturities that result in an imbalance favoring bilirubin production over hepatic enteric bilirubin clearance (Fig. 84.1). The equation below summarizes the interactions among the rates of bilirubin production (a), the enterohepatic circulation of bilirubin (b), and bilirubin elimination (c), in determining the TSB at any postnatal time point *t*, where TSB₀ is the cord blood TSB (Valaes, 2001):

$$TSB_t = TSB_0 + \sum [a(t) + b(t) - c(t)]^{\Delta t}$$

A variety of clinical conditions can increase the bilirubin load or decrease bilirubin clearance and thereby contribute to neonatal hyperbilirubinemia in any given infant (Box 84.1). In a small fraction of neonates, a constellation of conditions may lead to hazardous levels of hyperbilirubinemia that pose a neurotoxic risk. Accelerated RBC turnover (hemolysis) plays a pivotal role in increasing the risk for subsequent severe hyperbilirubinemia and in potentiating the risk of bilirubin neurotoxicity. Treatment interventions are therefore recommended at a lower bilirubin level whenever hemolysis is present. Caretakers of neonates must therefore be attuned to identifying hemolytic disorders in the jaundiced neonate.

Hemolytic Disease—Increased Hepatic Bilirubin Load

The causes of hemolysis in the neonatal period can be broadly grouped into three major categories: (1) *heritable* defects in red cell metabolism, membrane structure, or hemoglobin; (2) *acquired* disorders; and (3) *immune*-mediated mechanisms (Box 84.1).

• **Fig. 84.1** Schematic of Bilirubin Production and Hepatic Bilirubin Clearance in Neonates. Heme, produced largely by the breakdown of red blood cells (RBCs), is catabolized by heme oxygenase to produce an equimolar amount of carbon monoxide (CO) and biliverdin; the latter is reduced to unconjugated bilirubin by biliverdin reductase. Unconjugated bilirubin is taken up by the hepatocyte via facilitated diffusion, bound to glutathione S-transferase (ligandin), and conjugated with glucuronic acid by hepatic uridine diphosphate-glucuronosyltransferase 1A1 (UGT1A1). Conjugated bilirubin is excreted into bile via multidrug resistance protein-2, a portion of which may be deconjugated by intestinal β -glucuronidase and reabsorbed into the portal circulation, enhancing the hepatic bilirubin load (enterohepatic circulation).

Red Cell Membrane Defects

Of the many red cell membrane defects that lead to hemolysis, only hereditary spherocytosis, elliptocytosis, stomatocytosis, and infantile pyknocytosis manifest themselves in neonates (Tuffy et al., 1959; Oski, 1993; Caprari et al., 1997). Establishing a diagnosis of these disorders is often difficult because newborns normally exhibit a marked variation in red cell membrane size and shape (Oski, 1982a, 1993; Zipursky et al., 1983; Stockman, 1988). Spherocytes, however, are not often seen on RBC smears of hematologically normal newborns and when prominent suggest a diagnosis of hereditary spherocytosis, as does an elevated mean corpuscular hemoglobin concentration (MCHC >36.5 – 37 g/dL) or MCHC to mean corpuscular volume (MCV) ratio (MCHC/MCV >0.36) (Christensen et al., 2015). Given the likelihood of autosomal dominant inheritance, a positive family history can often be elicited. The diagnosis of hereditary spherocytosis can be confirmed using the incubated osmotic fragility test coupled with fetal red cell controls or eosin-5-maleimide flow cytometry (Christensen et al., 2015). One must rule out symptomatic ABO hemolytic disease by performing a direct Coombs test as infants so affected can manifest prominent microspherocytosis (Becker et al., 1993). Moreover, hereditary spherocytosis and symptomatic ABO hemolytic disease can occur in the same infant and result in anemia and severe hyperbilirubinemia (Trucco and Brown, 1967).

Hereditary elliptocytosis and stomatocytosis are rare but reported causes of hemolysis in the newborn period (Oski, 1993). Infantile pyknocytosis is a transient red cell membrane abnormality manifesting itself during the first few months of life. The pyknocyte, an

• BOX 84.1 Causes of Indirect Hyperbilirubinemia in Neonates

A. Increased Hepatic Bilirubin Load

- Hemolytic disease—immune mediated (positive direct Coombs test)
 - Rhesus isoimmunization
 - ABO incompatibility
 - Minor blood group incompatibility
- Hemolytic disease—red blood cell enzyme abnormalities
 - Glucose-6-phosphate dehydrogenase deficiency
 - Pyruvate kinase deficiency
- Hemolytic disease—red blood cell membrane defects
 - Hereditary spherocytosis
 - Elliptocytosis
 - Stomatocytosis
 - Pyknocytosis
- Hemolytic disease—hemoglobinopathies
 - Alpha-thalassemia
 - Gamma-thalassemia
- Extravascular blood (e.g., cephalohematoma)
- Polycythemia
- Enhanced enterohepatic bilirubin circulation
 - Intestinal obstruction, pyloric stenosis
 - Ileus, meconium plugging, cystic fibrosis
 - Breast-milk feeding

B. Decreased Hepatic Bilirubin Clearance

- Prematurity including late-preterm gestation
- Hormonal deficiency
 - Hypothyroidism
 - Hypopituitarism
- Impaired hepatic bilirubin uptake
 - Patent ductus venosus
 - SLC01B1 gene polymorphisms
- Disorders of bilirubin conjugation—UGT1A1 gene variants
 - Crigler–Najjar syndrome type I
 - Crigler–Najjar syndrome type II (Arias disease)
 - Gilbert disease
- Enhanced enterohepatic circulation
 - Intestinal obstruction, pyloric stenosis
 - Ileus, meconium plugging, cystic fibrosis
 - Breast-milk feeding

SLC01B1, Solute carrier organic anion transporter 1B1; UGT1A1, uridine diphosphate glucuronosyltransferase 1A1.

irregularly contracted red cell with multiple spines, can normally be observed in premature infants where as many as 5% of red cells may manifest this morphologic variant (Tuffy et al., 1959). In newborns affected with infantile pyknocytosis, however, up to 50% of red cells exhibit the morphologic abnormality, associated with anemia, a reticulocytosis, and hyperbilirubinemia that can be severe enough to require control by exchange transfusion (Tuffy et al., 1959). Red cells transfused into affected infants become pyknocytic and have a shortened life span, suggesting that an extra corpuscular factor mediates the morphologic alteration (Tuffy et al., 1959; Keimowitz and Desforjes, 1965; Ackerman, 1969). Whatever the mechanism underlying infantile pyknocytosis, the disorder tends to resolve after several months of life. Pyknocytosis may also occur in other conditions, including glucose-6-phosphate dehydrogenase (G6PD) deficiency and hereditary elliptocytosis, and these must be excluded before a diagnosis of infantile pyknocytosis is made.

Red Cell Enzyme Deficiencies

The two most common red cell enzyme defects that can lead to hyperbilirubinemia in the neonatal period are G6PD (Beutler, 1994; Valaes, 1994, 2000; MacDonald, 1995; Kaplan et al., 1998, 2004; Luzzatto, 2003) and pyruvate kinase deficiency (Mentzer, 2003; Rider et al., 2011). Of these, pyruvate kinase deficiency is far less frequent; it is an autosomal recessive disorder largely confined to populations in which consanguinity is prevalent, including newborns of Amish descent and other isolated communities (Christensen et al., 2010, 2011; Rider et al., 2011). Pyruvate kinase deficiency often presents with anemia, reticulocytosis, and severe hyperbilirubinemia (Osaki 1982a; Mentzer, 2003). Its importance derives from the fact that a full third of affected infants require exchange transfusion to control their hyperbilirubinemia (Matthay and Mentzer, 1981), and kernicterus is a real risk (Osaki et al., 1964; Christensen et al., 2011; Rider et al., 2011). The diagnosis of pyruvate kinase deficiency is often difficult, as the enzymatic abnormality is frequently not simply a quantitative defect but may involve abnormal enzyme kinetics or an unstable enzyme that decreases in activity as the red cell ages. The diagnosis of pyruvate kinase deficiency should be considered whenever marked hyperbilirubinemia and a picture of nonspherocytic, Coombs negative hemolytic anemia is observed.

Glucose-6-Phosphate Dehydrogenase Deficiency

G6PD deficiency is an X-linked enzymopathy affecting hemizygous males, homozygous females, and a subset of heterozygous females (via X chromosome inactivation) and is an important cause of hazardous hyperbilirubinemia and kernicterus worldwide, including the United States. Although most prevalent in Africa, the Middle East, East Asia, and the Mediterranean, G6PD deficiency has evolved into a global neonatal problem as a result of past and present migration patterns, the slave trade, and intermarriage (Beutler, 1994; Valaes, 1994, 2000; Kaplan et al., 1998, 2004). It is a noteworthy contributor to endemic rates of bilirubin encephalopathy in several developing countries (e.g., Nigeria, where ~3% of neonatal hospital admissions evidence bilirubin encephalopathy) (Oguniesi et al., 2007) and accounts for a substantial and disproportionate number of neonates with kernicterus in the United States Pilot Kernicterus registry (20.8% of all reported cases) (Bhutani et al., 2004; Johnson et al., 2009). The majority of these kernicterus cases have been in African-American neonates (Watchko, 2010), an at-risk population given G6PD deficiency prevalence rates in the United States of 12.2% for African-American males and 4.1% for African-American females (Chinevere et al., 2006). Other subgroups at risk for G6PD deficiency include newborns of East Asian, Greek, Italian (especially Sardinia and Sicily), and Middle Eastern descent (Kaplan et al., 2004).

In this regard, G6PD is remarkable for its genetic diversity (more than 370 variants have been described) (Beutler, 2008), and those mutations seen in the United States include among numerous others the (1) African A variants, a group of double site mutations all of which share the adenine(A)376guanine (G) variant (also known as G6PD A+ when expressed alone; a nondeficient variant) coupled most commonly with the G202A mutation (G202A;A376G, known as G6PD A-) but on occasion with the thymine (T)968cytosine (C) variant (T968C;A376G; also known as G6PD Betica), or the G680T mutation (G680T;A376G); (2) the Mediterranean (C563T) mutation; (3) the Canton (G1376T) mutation; and (4) the Kaiping (G1388A) variant (Beutler, 1994; Lin et al., 2005).

G6PD is critical to the redox metabolism of red blood cells, and G6PD deficiency may be associated with acute severe hemolysis

Adapted from Osaki FA, Nalman JL. Hematologic Problems in the Newborn, 2nd ed. Philadelphia, PA: WB Saunders; 1972 and from Valaes F. Severe neonatal jaundice associated with glucose-6-phosphate dehydrogenase deficiency: Pathogenesis and global epidemiology. *Acta Paediatr Suppl.* 1994;394:58–76.

in newborns following exposure to oxidative stress. Reported hemolytic triggers in G6PD deficiency are outlined in Box 84.2. A sudden, often rapid exponential rise in TSB to potentially hazardous levels may occur and result in kernicterus that may not always be preventable (Valaes, 1994; Kaplan et al., 1998, 2004; Watchko, 2010). Severe jaundice rather than anemia may predominate in the clinical presentation (Valaes, 1994; Kaplan et al., 2008a). In some neonates, G6PD deficiency and hepatic uridine diphosphate-glucuronosyltransferase 1A1 gene (*UGT1A1*) polymorphisms of Gilbert syndrome that limit hepatic bilirubin conjugation combine to significantly increase the risk of hyperbilirubinemia (Kaplan et al., 1997). These variants include the promoter variant *UGT1A1**28 (Valaes 1994, 2000; Kaplan et al., 1997, 2004) and coding sequence variant *UGT1A1**6 (Huang et al., 2002a). Kaplan et al. (1997) have demonstrated a dose-dependent genetic interaction between the *UGT1A1**28 promoter variant and G6PD deficiency that substantially increases neonatal hyperbilirubinemia risk. Details regarding this icterogenic genetic interaction and other aspects of *UGT1A1* gene variants in neonates are described later under Hepatic Bilirubin Conjugation. Coexistent nongenetic factors may also impact hyperbilirubinemia risk in G6PD-deficient neonates, as

shown in those who are also late-preterm and breastfed (Kaplan et al., 2006).

Caretakers must have a high index of suspicion for G6PD deficiency in populations at increased risk (Mediterranean region, Africa, the Middle East, Asia) and in particular the African-American neonate with significant hyperbilirubinemia (Watchko, 2010). Although there has been discussion on the potential utility of screening for G6PD deficiency in the United States, no consensus has emerged on whether or how best to screen, and point-of-care testing during birth hospitalization is not routinely practiced (Watchko et al., 2013). One targeted screening program at a US hospital with a large at-risk population, however, demonstrates the feasibility and utility of identifying G6PD-deficient newborns (Nock et al., 2011). Reports from abroad (e.g., Israel, Singapore, and Taiwan) (Padilla and Therrell, 2007; Kaplan et al., 2008b) show that point-of-care G6PD screening strategies are associated with reductions in the prevalence of severe hyperbilirubinemia and kernicterus.

Heritable Causes of Hemolysis—Hemoglobinopathies

Defects in hemoglobin structure or synthesis are rare disorders that infrequently manifest themselves in the neonatal period. Of these, the α -thalassemia syndromes are the most likely to be clinically apparent in newborns. Each human diploid cell contains four copies of the α -globin gene, and thus four α -thalassemia syndromes have been described reflecting the presence of defects in 1, 2, 3, or 4 α -globin genes. Silent carriers have one abnormal α -globin chain and are asymptomatic. α -Thalassemia trait is associated with two α -thalassemia mutations, is not associated with hemolysis in newborns, and is common in black populations and detected by a low MCV of less than $95 \mu\text{m}^3$ (normal infants $100\text{--}120 \mu\text{m}^3$) (Schmaier et al., 1973). Hemoglobin H disease results from the presence of three thalassemia mutations and can cause hemolysis and anemia in neonates (Pearson, 1982). Homozygous α -thalassemia (total absence of α -chain synthesis) results in profound hemolysis, anemia, hydrops fetalis, and almost always stillbirth or death in the immediate neonatal period.

The pure β -thalassemias do not manifest themselves in the newborn period, and the γ -thalassemias are (1) incompatible with life (homozygous form), (2) associated with transient mild-to-moderate neonatal anemia if one or two genes are involved that resolves when β -chain synthesis begins, or (3) in combination with impaired β -chain synthesis, associated with severe hemolytic anemia and marked hyperbilirubinemia (Oort et al., 1981).

Acquired Causes of Hemolysis

Acquired causes of hemolysis comprise a miscellaneous group of disorders, which include among others the (1) microangiopathic hemolysis associated with disseminated intravascular coagulation or hemangiomas and (2) infection (bacterial sepsis or congenital infections) (Oski, 1982a). The mechanism(s) underlying the hemolytic process in the latter is not fully understood but may also serve as a hemolytic trigger in G6PD deficiency.

Immune-Mediated Hemolytic Disease

Immune-mediated disorders are the most common cause of hemolysis in neonates and should be suspected when there is (1) a heterospecific mother–infant pair where the infant expresses a

red cell antigen(s) foreign to the mother, (2) the presence of a maternal antibody directed to the infant RBC antigen, (3) and a positive direct Coombs test in the neonate indicating maternal antibody bound to the infant RBC.

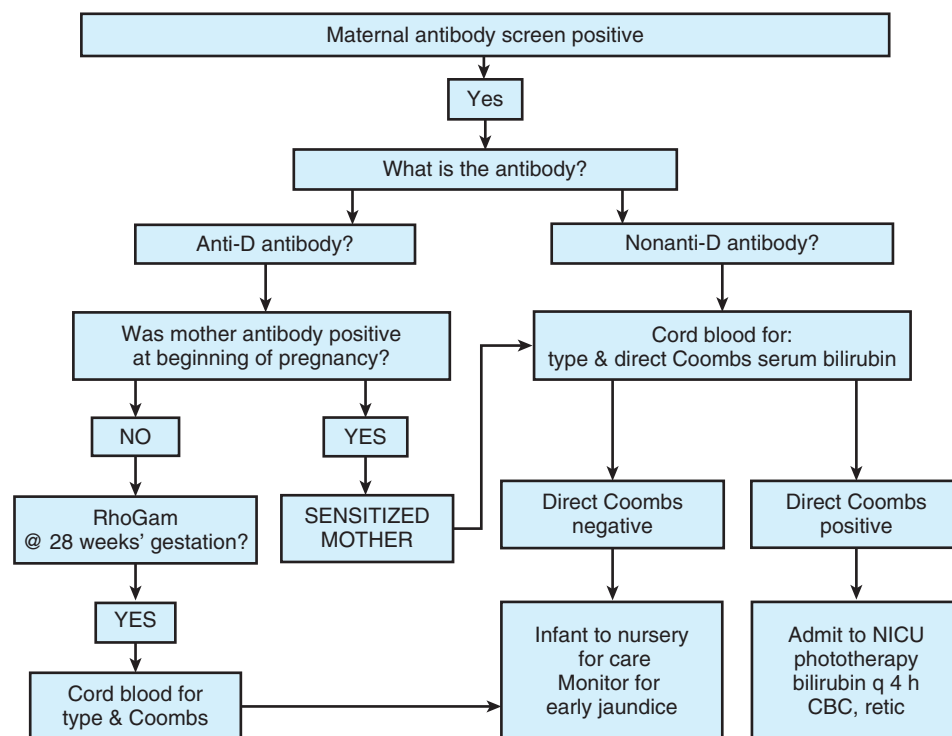

Non-ABO Alloantibodies

A priority in evaluating every newborn is knowledge of the maternal blood type and the maternal antibody screen routinely performed at maternal registration upon pregnancy diagnosis to identify non-ABO alloantibodies in the maternal serum that may pose a risk for hemolytic disease in the newborn. In addition, Rhesus (Rh)-D negative women who have a negative antibody screen at registration will have a repeat screen at 24–28 weeks' gestation before Rhogam (RhD-immunoglobulin, manufactured by CSL Biehring AG, Bern, Switzerland) administration and another screen at delivery along with a type and Coombs test on the infant to determine the need for postpartum Rhogam.

In addition to the classic Rhesus hemolytic disease of the newborn (HDN) secondary to Rh-D isoimmunization, alloantibodies directed to non-D Rhesus antigens and a broad range of non-Rhesus blood group (minor) antigens are seen. Increasingly the latter two categories comprise a clinically relevant proportion of HDN. The incidence of clinically significant sensitization to the minor blood group antigens as determined by metaanalysis approximates 1:330 pregnancies (Solola et al., 1983). Only a review of the maternal antibody screen and the direct Coombs test on the infant will uncover such cases. Fig. 84.2 outlines an approach to the evaluation and management of the neonate born to a mother with a positive antibody screen. A blood type and direct Coombs test are indicated at delivery (cord or infant blood) for all infants born to women with a positive antibody screen.

Interpreting the results of the maternal antibody screen by neonatal caregivers is critical in identifying mothers who carry a non-ABO alloantibody, several of which can cause moderate-to-severe HDN. Table 84.1 outlines several clinical scenarios in which the maternal antibody screen is positive, accompanied by the likely clinical explanation for the positive screen (Watchko, 2015). The only scenario shown that does not indicate maternal sensitization is that secondary to Rhogam administration. The latter positive anti-D maternal antibody screen must be distinguished from the occurrence of late Rh-D sensitization by confirming that the mother was anti-D antibody negative before Rhogam administration and that she did indeed receive Rhogam. At times, the infant will also have a positive direct Coombs test secondary to maternal Rhogam administration (Bowman et al., 1978; Judd, 2001; Maayan-Metzger et al., 2001). This finding is generally not thought to indicate a hemolytic risk (Bowman et al., 1978; Judd, 2001; Maayan-Metzger et al., 2001; Dillon et al., 2011), albeit one recent case report suggesting in rare circumstances it may (Cohen et al., 2014). The latter has yet to be confirmed (Watchko, 2014b).

It is also important to note that Rh-D positive infants delivered to Rh-D negative women during the first isoimmunized pregnancy (conversion from negative to positive maternal antibody titer in that pregnancy) are at an approximately 20% risk of developing HDN requiring treatment, including the possibility of an exchange transfusion (Goplerud et al., 1973). An infant born of a pregnancy during which maternal antibody conversion occurs will by definition carry the foreign antigen and may have a positive direct Coombs test. Such infants are at risk of HDN, and should be monitored closely for severe hyperbilirubinemia with serial TSB measurements and not discharged early from the birth hospital.

• **Fig. 84.2** An Approach to the Evaluation and Management of the Neonate Who Is Born to a Mother With a Positive Antibody Screen. Care must be taken to (1) distinguish passive anti-D as a result of Rhogam administration from sensitization to anti-D in the context of a positive maternal antibody screen to anti-D and (2) identify all non-D alloantibodies. CBC, Complete blood count; NICU, neonatal intensive care unit. (Courtesy of Kalyani Vats and Jon F. Watchko, Magee-Womens Hospital. See also text and Table 84.1.)

TABLE 84.1

Interpreting Maternal Antibody Status in Rhesus-D Negative Women at Delivery

| Maternal Antibody Status at Beginning of Pregnancy | Maternal Antibody Status at 24–28 Weeks Prior to Rhogam | Was Rhogam Administered? | Maternal Antibody Status at Delivery | Maternal Antibody | Diagnosis | Infant at Risk for Hemolytic Disease of the Newborn |
|--|---|--------------------------|--------------------------------------|-------------------|-------------------------------------|---|
| Negative | Negative | Yes | Positive | Anti-D | Passive anti-D; Rhogam effect | Unlikely ^a |
| Negative | Negative | No | Positive | Anti-D | Late sensitization to Rh-D | Yes |
| Negative | Positive | No | Positive | Anti-D | Early sensitization to Rh-D | Yes |
| Positive | Positive | No | Positive | Anti-D | Sensitized pregnancy to Rh-D | Yes |
| Negative | Negative | Yes | Positive | Non-D antibody | Late sensitization to non-D antigen | Yes |

^aAt times, the infant will also have a positive direct Coombs test secondary to maternal Rhogam administration (Bowman et al., 1978; Judd 2001; Maayan-Metzger et al., 2001). This finding is generally not thought to indicate a hemolytic risk (Bowman et al., 1978; Judd 2001; Maayan-Metzger et al., 2001) albeit reports suggest in rare circumstances it may (Dillon et al., 2011; Cohen et al., 2014). The latter has yet to be confirmed (Watchko and Triulzi, 2014).

From Watchko JF. Common hematologic problems in the newborn nursery. *Pediatr Clin North Am.* 2015; 62:509–524 with permission.

ABO Hemolytic Disease

Hemolytic disease related to ABO incompatibility is generally limited to mothers who are blood group O and infants of blood group A or B (Naiman, 1982; Ozolek et al., 1994). Although this association exists in approximately 15% of pregnancies, only a fraction of infants born in this context will develop significant hyperbilirubinemia (Naiman, 1982; Ozolek et al., 1994). Despite

the difficulty in predicting its development, symptomatic ABO hemolytic disease does occur. The diagnosis should be considered in infants who develop marked jaundice in the context of ABO incompatibility that is generally accompanied by a positive direct Coombs test and prominent microspherocytosis on red cell smear (Naiman, 1982). The hyperbilirubinemia seen with symptomatic ABO hemolytic disease is often detected within the first 12–24

hours of life (“icterus praecox” [Halbrecht, 1944]). Although usually controlled with intensive phototherapy alone (Naiman, 1982), a few affected infants develop hyperbilirubinemia to levels requiring exchange transfusion (Mollison, 1983). Routine screening of all ABO-incompatible cord blood has been recommended in the past and remains common practice in many nurseries (Leistikow et al., 1995). The current literature (Quinn et al., 1988; Ozolek et al., 1994; Leistikow et al., 1995), however, suggests that such routine cord blood screening is not warranted given the low yield and cost, consistent with the position of the American Association of Blood Banks (Judd et al., 1990). This recommendation assumes that universal prebirth hospitalization discharge bilirubin screening is used to help assess the risk of subsequent severe hyperbilirubinemia (Maisels et al., 2009b). A blood type and Coombs test are indicated in the evaluation of any newborn with early and/or clinically significant jaundice.

Infants born of ABO-incompatible mother–infant pairs who have a negative direct Coombs test appear to be at no greater risk for developing hyperbilirubinemia than their ABO-compatible counterparts (Ozolek et al., 1994), and the development of significant hyperbilirubinemia in such neonates should prompt an evaluation for a cause other than isoimmunization (Herschel et al., 2002). Similarly, group A or B infants born to incompatible group B or A mothers are not likely to manifest symptomatic ABO hemolytic disease, and less than 1% will have a positive direct Coombs test (Ozolek et al., 1994).

Decreased Hepatic Bilirubin Clearance

Hepatic Bilirubin Uptake

During intrauterine life, fetal bilirubin is removed by the placenta, metabolized, and excreted by the maternal liver. Blood flow through the hepatic arteries develops only in the first week of extrauterine life, and the ductus venosus may remain partially patent for several days, allowing blood to bypass the liver. Unconjugated bilirubin also appears to be a substrate for the solute carrier organic anion transporter 1B1 (SLCO1B1), a sinusoidal transporter that facilitates the hepatic uptake of a broad range of endogenous substrates and xenobiotics in an adenosine triphosphate-independent fashion (Cui et al., 2001). It follows that delayed developmental expression of *SLCO1B1* and the presence of nonsynonymous *SLCO1B1* gene variants may impact hepatic bilirubin uptake and bilirubin metabolism of neonates (Huang et al., 2004; Daood and Watchko, 2006). These factors may contribute to a delay in the plasma clearance of bilirubin.

Hepatic Bilirubin Conjugation

The bilirubin-conjugating capacity of infants is dependent on the activity of hepatic uridine diphosphate-glucuronosyltransferase 1A1 (UGT1A1), which is developmentally expressed at 0.1% of adult levels at 17–30 weeks’ gestation, increasing to 1% of adult values between 30 and 40 weeks’ gestation, and reaching adult levels only at 14 weeks of postnatal life (Kawade and Onishi, 1981; Coughtrie et al., 1988). This graded upregulation of hepatic UGT1A1 activity over the first few days of life may be induced by TSB itself and is noted following birth, regardless of the newborn’s gestational age. Induction of *UGT1A1* is also enhanced by phenobarbital via the phenobarbital responsive enhancer module (PBREM) in the *UGT1A1* gene promoter element. A nonsynonymous polymorphism of the *UGT1A1* PBREM (T3279G) is

associated with an increased risk of hyperbilirubinemia (Sugatani et al., 2002).

In addition to the developmentally modulated postnatal transition in hepatic bilirubin UGT1A1 activity, there are congenital inborn errors of *UGT1A1* expression, commonly referred to as the indirect hyperbilirubinemia syndromes (Valaes, 1976). These include the Crigler–Najjar type I and II (Arias) syndromes and Gilbert syndrome (Table 84.2). Infants with Crigler–Najjar type I have complete absence of bilirubin UGT1A1 activity and are at significant risk for bilirubin encephalopathy and its neurodevelopmental sequelae (Crigler and Najjar, 1952; Strauss et al., 2006). Inherited in an autosomal recessive pattern, the type I syndrome has marked genetic heterogeneity (Clarke et al., 1997). Currently, at least 85 different genetic mutations have been identified in Crigler–Najjar type I syndrome, typically nonsense or “stop” mutations in nature (Clarke et al., 1997).

Phototherapy is the mainstay of treatment for infants and children with Crigler–Najjar type I syndrome, although neonates may develop hazardous hyperbilirubinemia necessitating exchange transfusion. Liver transplantation is the only current definitive therapeutic intervention for this disorder (Shevell et al., 1987). Human hepatocyte transplantation holds promise to enhance hepatic UGT1A1 activity as an alternative approach that could obviate the need for liver transplantation. The ultimate treatment for this inborn error of bilirubin *UGT1A1* expression will reside in the development of an effective gene therapy strategy (Roy-Chowdhury et al., 2001; Bortolussi et al., 2014).

In contrast, the Arias syndrome, typified by more moderate levels of indirect hyperbilirubinemia as well as low but detectable hepatic bilirubin UGT1A1 activity, appears in the majority of cases to be mediated by missense mutations in the *UGT1A1* gene (Clarke et al., 1997). Phenobarbital can be trialed to induce residual UGT1A1 activity. These rare but important clinical syndromes must be included in the differential diagnosis of prolonged marked indirect hyperbilirubinemia.

Gilbert Syndrome

Gilbert syndrome, originally described at the turn of the century (Gilbert and Lereboullet, 1901), is far more common and characterized by mild, chronic, or recurrent unconjugated hyperbilirubinemia in the absence of liver disease or overt hemolysis (Gourley, 1994). Hepatic *UGT1A1* activity is reduced at least 50% in affected subjects, and more than 95% of their total serum bilirubin is unconjugated (Gourley, 1994). Gilbert syndrome affects approximately 9% of the population, and its genetic basis in Caucasians and African Americans is an abnormal *UGT1A1* promoter element (Bosma et al., 1995). More specifically, the variant promoter contains a two base-pair addition (TA) in the TATAA promoter element, giving rise to 7 (A[TA]₇TAA) rather than the more usual 6 (A[TA]₆TAA) repeats and is termed *UGT1A1**28. The extra TA repeat (A[TA]₇TAA) impairs proper message transcription and accounts for a reduced UGT1A1 activity (Bosma et al., 1995). As the repeat number increases, UGT1A1 activity decreases (Beutler et al., 1998). Subjects with Gilbert syndrome are homozygous for the *UGT1A1**28 variant promoter, providing a unique genetic marker for this disorder (Bosma et al., 1995).

Investigators had long speculated that Gilbert syndrome might contribute to indirect hyperbilirubinemia in the newborn period (Valaes, 1976; Odell, 1980; Oski, 1984), and clinical reports show that neonates with *UGT1A1**28 have accelerated jaundice, decreased fecal excretion of bilirubin monoglucuronides and diglucuronides

TABLE
84.2**Congenital Nonhemolytic Unconjugated Hyperbilirubinemia: Clinical Syndromes**

| Characteristic | SEVERITY | | |
|------------------------------------|---|---|--|
| | Marked Crigler–Najjar Type I | Moderate Crigler–Najjar Type II | Mild Gilbert Syndrome |
| Steady-state serum total bilirubin | >20 mg/dL | <20 mg/dL | <5 mg/dL |
| Range of bilirubin values | 14–50 mg/dL | 5.3–37.6 mg/dL | 0.8–10 mg/dL |
| Total bilirubin in bile | <10 mg/dL (increased with phototherapy) | 50–100 mg/dL | Normal |
| Conjugated bilirubin in bile | Absent | Present (only monoglucuronide) | Present (50% monoglucuronide) |
| Bilirubin clearance | Extremely decreased | Markedly decreased | 20–30% of normal |
| Hepatic bilirubin uptake | Normal | Normal | Reduced |
| Bilirubin UGT1A1 activity | None detected | None detected | Decreased |
| Genetics | Autosomal recessive | Heterogeneity of defect distinctly possible | Genetic polymorphisms: 1. Thymine-adenine (TA) ₇ and (TA) ₈ repeats in the <i>UGT1A1</i> promoter region. 2. G211A (Gly71Arg) <i>UGT1A1</i> coding sequence mutation identified in the Asian populations. 3. Linkage disequilibrium between (TA) ₇ /(TA) ₇ and T-3279G PBREM <i>UGT1A1</i> promoter polymorphisms |

(Bancroft et al., 1998), and modestly elevated postnatal TSB levels (Roy-Chowdhury et al., 2002). Others have failed to demonstrate a clinically significant effect of *UGT1A1**28 alone on peak TSB. However, the coupling of the *UGT1A1* promoter variant A(TA)₇TAA with icterogenic conditions, e.g., G6PD deficiency and hereditary spherocytosis, markedly increases a newborn's risk for severe hyperbilirubinemia (Kaplan et al., 1997; Iolascon et al., 1998). Several studies clearly demonstrate that the A(TA)₇TAA promoter variant is prevalent in breastfed infants who develop prolonged neonatal indirect hyperbilirubinemia (Maruo et al., 1999; Monaghan et al., 1999; Roy-Chowdhury et al., 2002). In Asian populations the nucleotide 211 guanine to adenine mutation (G71R) in the coding sequence of *UGT1A1* (*UGT1A1**6) appears to underlie the Gilbert phenotype and contribute to neonatal hyperbilirubinemia risk (Huang et al., 2002b, 2004; Huang, 2005). These studies taken together demonstrate that Gilbert syndrome is a contributing factor to neonatal jaundice.

Enhanced Enterohepatic Circulation

Intestinal reabsorption of bilirubin excreted into the intestine is enhanced in neonates, adding to their hyperbilirubinemia risk (Poland, Odell, 1971). Conjugated bilirubin, as either the monoglucuronide or diglucuronide, is unstable and can be spontaneously or enzymatically hydrolyzed back to unconjugated bilirubin via intestinal β-glucuronidase and readily reabsorbed through the mucosa. Two other factors accelerating the deconjugation of bilirubin glucuronides in the newborn intestine are the mildly alkaline pH of the proximal intestine, which facilitates nonenzymatic hydrolysis, and the predominance of monoglucuronides as the main excretion form of bilirubin in the first few days of life. Neonatal absorption

is also enhanced by the lack of intestinal flora, which metabolize conjugated bilirubin to the water-soluble and readily excretable breakdown products urobilin and stercobilin.

Other Clinically Relevant Icteric Conditions

Certain demographic, environmental, and genetic risk factors, among a myriad of icterogenic contributors, merit special clinical attention in addition to hemolytic conditions. Many have been characterized as major risk factors for the development of severe hyperbilirubinemia in the 2004 American Academy of Pediatrics (AAP) clinical practice guideline on hyperbilirubinemia management in infants of greater than 35 weeks' gestation (Box 84.3) (American Academy of Pediatrics, 2004). Although each holds the potential to be a singularly important contributor to an infant's hyperbilirubinemia, more often multiple risk factors are observed in combination (Newman et al., 2000; Huang et al., 2004) in marked hyperbilirubinemia. Indeed, in infants with peak TSB levels greater than or equal to 25 mg/dL (428 μmol/L), 88% had a least two and 43% had three or more identified risk factors in one report (Newman et al., 2000), and 58% with peak TSB greater than or equal to 20 mg/dL (342 μmol/L) had at least two risk factors in another (Huang et al., 2004). Data derived from hyperbilirubinemia risk instruments that incorporate several factors support the multifactorial pathogenesis of marked hyperbilirubinemia (Newman et al., 2000, 2005) and highlight the importance of two in particular: (1) late-preterm gestational age and (2) exclusive breastfeeding (Newman et al., 2000, 2005; Keren et al., 2008). These contributors and others of notable clinical impact are reviewed in further detail later.

• BOX 84.3 Major Risk Factors for Development of Severe Hyperbilirubinemia in Infants of Greater Than 35 Weeks' Gestation

Gestational age 35–36 weeks
 Exclusive breastfeeding, particularly if nursing is not going well and weight loss is excessive
 Blood group incompatibility with positive direct antiglobulin test, other known hemolytic disease (e.g., G6PD deficiency)
 East Asian race
 Jaundice observed in the first 24 hours
 Cephalohematoma or significant bruising
 Previous sibling received phototherapy
 PredischARGE TSB or TcB level in the high-risk zone (>95% on Bhutani nomogram)

G6PD, Glucose-6-phosphate dehydrogenase; TcB, transcutaneous bilirubin; TSB, total serum bilirubin.

• **Fig. 84.3** Risk of developing a total serum bilirubin (TSB) greater than or equal to 20 mg/dL (342 μ mol/L) as a function of gestational age (weeks) and percentile-based TSB measured at less than 48 hours using the Bhutani nomogram. (Modified from *Arch Pediatr Adolesc Med*. 2005;159(2):117, Copyright © 2005, American Medical Association. All rights reserved.)

Late-Preterm Gestation

Late-preterm ($34^{0/7}$ – $36^{6/7}$ weeks' gestation) infants evidence lower UGT1A1 enzyme activity (Kawade and Onishi, 1981; Kaplan et al., 2005) and a slower increase in UGT1A1 enzyme activity than their term counterparts during the first week of life (Kawade and Onishi, 1981). This exaggerated hepatic immaturity contributes to the greater prevalence, severity, and duration of neonatal jaundice in late-preterm infants (Watchko, 2006b). Indeed there is an approximately eightfold increased risk of developing a TSB of greater than or equal to 20 mg/dL (342 μ mol/L) in infants born at 36 weeks' gestational age (5.2%) as compared with those born at 41 or greater than or equal to 42 weeks' gestation (0.7% and 0.6%, respectively) (Newman et al., 1999). This gestational age effect is even more evident when examined as a function of hour-specific TSB risk zones using the Bhutani nomogram (Bhutani et al., 1999), as shown in Fig. 84.3 (Newman et al., 2005). The reported difficulty in visually assessing jaundice in late-preterm newborns (Keren et al., 2009) underscores the importance of routine birth hospitalization TSB or transcutaneous bilirubin (TcB) screening in this at-risk cohort (Maisels et al., 2009b).

Late-preterm neonates, because of their immaturity, often demonstrate less effective sucking and swallowing and may have difficulties achieving consistent nutritive breastfeeding (Wang et al., 2004), phenomena that may predispose to varying degrees of lactation failure. Suboptimal feeding was the leading reason for discharge delay during birth hospitalization in late-preterm neonates in one recent study (Wang et al., 2004). Pediatricians, therefore, need to be alert to the potential of suboptimal breast-milk feeding in late-preterm neonates and not be misled by the seemingly satisfactory breastfeeding efforts of late-preterm newborns during the birth hospitalization when limited colostrum volumes make it a challenge to adequately assess the effectiveness of breast-milk transfer (Neifert, 2001). Late-preterm infants who are breastfed merit timely post birth-hospitalization discharge follow-up and lactation support (Bhutani and Johnson, 2006; Watchko, 2006b; Maisels et al., 2009). Parental education (written and verbal) about neonatal jaundice and when to call the pediatrician is also important (American Academy of Pediatrics, 2004). A shortened hospital stay (<48 hours after delivery), although permitted for selected healthy term neonates, is not recommended for late-preterm neonates (American Academy of Pediatrics, 2007).

Late-preterm infants are disproportionately over-represented in the United States Pilot Kernicterus Registry, a database of voluntarily reported cases of kernicterus (Bhutani et al., 2004; Bhutani and Johnson, 2006; Johnson et al., 2009). Moreover, the registry demonstrates that late-preterm neonates show signs of bilirubin neurotoxicity at an earlier postnatal age than term newborns indirectly suggesting a greater vulnerability to bilirubin-induced brain injury (Bhutani and Johnson, 2006). Clinical hyperbilirubinemia management guidelines for late-preterm infants therefore recommend treatment at lower TSB thresholds than term newborns, a distinction that is an important component of the 2004 AAP practice guideline on neonatal jaundice (American Academy of Pediatrics, 2004). It is also important to note that (1) the management of late-preterm newborns born between $34^{0/7}$ and $34^{6/7}$ weeks' gestation is not addressed by the 2004 AAP guideline but is covered in a more recent approach to management (Maisels et al., 2012a), and (2) infants born between $37^{0/7}$ and $37^{6/7}$ weeks' gestation, although strictly defined as term, are characterized in the 2004 AAP guideline as medium to higher risk and are to be managed as "late-preterm" regarding phototherapy and exchange thresholds (American Academy of Pediatrics, 2004), reflecting the fact that neurotoxicity risk corresponds to gestational age.

Exclusive Breast-Milk Feeding

It is probably no coincidence that almost every reported case of kernicterus over the past three decades has been in a breastfed infant (Bhutani et al., 2004). As such, exclusive breast-milk feeding, particularly if nursing is not going well and weight loss is excessive, is listed as a major hyperbilirubinemia risk factor in the 2004 AAP practice guideline (American Academy of Pediatrics, 2004; Maisels et al., 2009a). What does the association between exclusive breast-milk feeding and kernicterus imply with respect to the etiopathogenesis of marked neonatal jaundice? Numerous studies have reported an association between breastfeeding and an increased incidence and severity of hyperbilirubinemia, both during the first few days of life and in the genesis of prolonged neonatal jaundice (Kivlahan and James, 1984; Linn et al., 1985; Maisels et al., 1986; Schneider, 1986; Hansen, 2001). A pooled analysis of 12 studies comprising over 8000 neonates showed a threefold greater incidence in TSB of greater than or equal to 12.0 mg/dL (205 μ mol/L) and

a sixfold greater incidence in levels of greater than or equal to 15 mg/dL (257 μ mol/L) in breastfed infants as compared with their formula-fed counterparts (Schneider, 1986). Others, however, report that if adequate breastfeeding is established and sufficient lactation support is in place breastfed infants should be at no greater risk for hyperbilirubinemia than their formula-fed counterparts (De Carvalho et al., 1982; Nielsen et al., 1987; Yamauchi and Yamanouchi, 1990; Rubaltelli, 1993). The later studies suggest that many breastfed infants who develop marked neonatal jaundice do so in the context of a delay in lactation or varying degrees of lactation failure. Indeed, an appreciable percentage of the breastfed infants who develop kernicterus have been noted to have inadequate intake and variable but substantial degrees of dehydration and weight loss (Maisels and Newman, 1995; Johnson et al., 2002; Bhutani et al., 2004). Inadequate breast-milk intake in addition to contributing to dehydration can further enhance hyperbilirubinemia by increasing the enterohepatic circulation of bilirubin and resultant hepatic bilirubin load (Maisels, 2000; Bertini et al., 2001). Breastfeeding-associated jaundice, however, is not associated with increased bilirubin production (Stevenson et al., 1980).

Lactation failure, however, is not uniformly present in affected infants, suggesting that other mechanism(s) may be operative in breastfeeding-associated jaundice. Breast-milk feeding may act as an environmental modifier for selected genotypes and thereby potentially predispose to the development of marked neonatal jaundice (Watchko et al., 2012). In one report the risk of developing a TSB greater than or equal to 20 mg/dL (342 μ mol/L) associated with breast-milk feeding was enhanced 22-fold when combined with expression of *UGT1A1**6 or *SLCO1B1**1b (Huang et al., 2004) and increased 88-fold when breast-milk feedings were combined with both *UGT1A1* and *SLCO1B1* variants (Huang et al., 2004). Several others have reported an association between prolonged (>14 days) breast-milk jaundice and expression of the *UGT1A1* gene promoter variant *UGT1A1**28 (Maruo et al., 1999; Monaghan et al., 1999). While recognizing the relationship between breast-milk feeding and jaundice, the benefits of breast-milk feeds far outweigh the related risk of hyperbilirubinemia. Cases of severe neonatal hyperbilirubinemia with suboptimal breast-milk feedings underscore the need for effective lactation support and timely follow-up examinations.

East Asian Ethnicity

Neonates of East Asian ethnicity encompassing the populations of mainland China, Hong Kong, Japan, Macau, Korea, and Taiwan demonstrate a higher incidence of hyperbilirubinemia than others (Newman et al., 1990) and an overall increased risk for a TSB of greater than or equal to 20 mg/dL (342 μ mol/L) (odds ratio [OR] 3.1, confidence interval [CI] 1.5–6.3) (Newman et al., 2000). As such, East Asian ancestry is listed as a major risk factor for severe hyperbilirubinemia in the 2004 AAP clinical practice guideline (American Academy of Pediatrics, 2004). Investigators have speculated as to the nature of this phenomenon, invoking potential population differences in the incidence of ABO hemolytic disease and G6PD deficiency as well as environmental exposures to Chinese materia medica among others (Ho, 1992). There is little doubt that G6PD deficiency is an important contributor to hyperbilirubinemia risk in East Asian newborns. Innate ethnic variation in hepatic bilirubin clearance (Ho, 1992) also contributes to the biologic basis of hyperbilirubinemia risk in Asian newborns, as revealed by genetic analysis of enzymatic variants that modulate bilirubin metabolism. Four different *UGT1A1* coding sequence

variants: (1) G211A (*UGT1A1**6), (2) C686A (*UGT1A1**27), (3) C1091T (*UGT1A1**73), and (4) T1456G (*UGT1A1**7) have been described in East Asian populations, each associated with a Gilbert syndrome phenotype (Huang et al., 2000, 2004). Of these, the *UGT1A1**6 variant is predominant, with an allele frequency of 11%–13% in East Asians (Huang et al., 2000) (as high as 30% in neonates with hyperbilirubinemia \geq 15 mg/dL [257 μ mol/L]) (Huang et al., 2002a) and an associated significant decrease in *UGT1A1* enzyme activity (Yamamoto et al., 1998). Hepatic *SLCO1B1* gene variants are also prevalent in East Asian populations (Huang et al., 2004; Kim et al., 2008) and the *SLCO1B1**1b variant was demonstrated to enhance neonatal hyperbilirubinemia risk (Huang et al., 2004). As noted in the section on breast-milk feeding earlier, coupling *UGT1A1* and *SLCO1B1* variants together enhances hyperbilirubinemia risk, one that is further increased when that infant is also exclusively breastfed (Huang et al., 2004).

Jaundice Observed in the First 24 Hours of Life

Jaundice appearing in the first 24 hours of life has long been regarded as an abnormal clinical finding and an indication for a serum bilirubin measurement (American Academy of Pediatrics, 2004). Approximately 2.8% of newborns will evidence jaundice within 18 hours and 6.7% within 24 hours of life (Newman et al., 2002). As contrasted with nonjaundiced newborns on the first day of life, newborns with overt jaundice in the first 24 hours of life are more likely to receive phototherapy (18.9% vs 1.7%; relative risk [RR] 10.1, 95% CI 4.2–24.4) and to develop a TSB greater than or equal to 25 mg/dL (428 μ mol/L) (OR 2.9, 95% CI 1.6–5.2) (Newman et al., 2002). Hemolytic disease, immune-mediated and otherwise, should be a diagnostic consideration in any infant with early clinical jaundice.

Cephalohematoma or Significant Bruising

Internal hemorrhage, ecchymosis, and other extravascular blood collections will enhance bilirubin production and the bilirubin load on the liver. Extravascular red cells have a markedly shortened life span and their heme fraction is quickly catabolized to bilirubin by tissue macrophages that contain heme oxygenase and biliverdin reductase (Odell, 1980). Thus cephalohematoma, subdural hemorrhage, massive adrenal hemorrhage, and marked bruising can be associated with increased serum bilirubin levels and typically manifest 48–72 hours following the extravasation of blood (Odell, 1980). This temporal pattern is consistent with the evolution of ecchymosis and bilirubin formation in situ and also accounts for why extravascular blood can cause prolonged indirect hyperbilirubinemia (Odell, 1980). An unusual but dramatic example of how extravascular blood can contribute to the genesis of hyperbilirubinemia is found in reports of marked jaundice associated with the delayed absorption of intraperitoneal blood in infants who received fetal intraperitoneal red cell transfusions (Wright et al., 1982; Rajagopalan and Katz, 1984). In one such case, 13 exchange transfusions were necessary to control the hyperbilirubinemia that resolved only when approximately 87 cc of packed red cell were evacuated from the intraperitoneal cavity (Wright et al., 1982). In this instance, the intraperitoneal blood hematocrit of 60% had the potential to contribute up to approximately 600 mg of bilirubin to the infant's bilirubin load over time. Although other causes of extravasation generally are not associated with such large amounts of sequestered blood, they can nevertheless contribute to the development of jaundice.

Previous Sibling Treated With Phototherapy

A history of a previous sibling treated with phototherapy is an identified risk factor for hyperbilirubinemia (Gale et al., 1990; Newman et al., 2000), in particular bilirubin concentrations greater than 15 mg/dL (257 μ mol/L) (Khoury et al., 1988). This relationship may reflect recurrent ABO or Rh hemolytic disease (Maisels, 1982) or exposure to a common environmental factor in addition to a shared genetic background (Gale et al., 1990). It is known that the recurrence rate of ABO hemolytic disease is high: 88% in those infants of the same blood type as their index sibling, with almost two-thirds of the affected infants requiring treatment (Katz et al., 1982). An excess risk in siblings independent of hyperbilirubinemia risk factors expected to recur in sibships including breastfeeding, lower gestational age, and hemolytic disease, however, suggests that genetic effects play an important role (Khoury et al., 1988; Gale et al., 1990). Consistent with this hypothesis, there is a higher concordance level in TSB between monozygotic (identical) than dizygotic (fraternal) twins when controlled for confounders that modulate neonatal bilirubinemia (Ebbesen and Mortensen, 2003).

African-American Ethnicity

African-American neonates demonstrate a lower overall incidence of significant hyperbilirubinemia, a lower risk for TSB greater than 20 mg/dL, comprise approximately 12% of the US population, and yet account for more than 25% of kernicterus cases in the United States (Watchko, 2010). An explanation for this discordancy has recently emerged (Wickremasinghe et al., 2013). Using a large neonatal cohort, Wickremasinghe et al. (2013) reported that black infants, despite having a reduced risk of TSB greater than 20 mg/dL, actually have a fourfold increased risk for a TSB greater than

or equal to 30 mg/dL than other groups. Black race is not protective against hazardous (>30 mg/dL) hyperbilirubinemia, levels that pose the greatest risk of bilirubin-induced brain injury. G6PD deficiency is a plausible contributor to this pattern, but no effect modification by sex expected in an X-linked disorder was observed (Wickremasinghe et al., 2013). Regardless, black race can no longer be considered a factor associated with decreased hyperbilirubinemia risk (American Academy of Pediatrics, 2004), and black infants must be monitored for hyperbilirubinemia at least as closely as other neonates (Wickremasinghe et al., 2013). Some would caution that African-American neonates with overt jaundice (male or female) merit special attention and follow-up because such infants represent exceptions, a subset of which might be G6PD deficient. Consistent with this assertion, Kaplan et al. (2004) reported that 48.4% of G6PD-deficient African-American neonates developed a TSB greater than 75% (high-intermediate) and 21.9% a TSB greater than 95% (high) risk zones on the Bhutani nomogram, respectively. In contrast, Keren et al. (2008) report that neither the presence of a G6PD mutation or overt clinical jaundice was associated with the development of significant hyperbilirubinemia in black infants or black male infant cohorts.

Combining Clinical Risk Factor Assessment With PredischARGE Bilirubin Measurement

Several clinical studies show that combining clinical risk factor analysis with a birth hospitalization predischARGE measurement of TSB or TcB significantly improves the prediction of subsequent hyperbilirubinemia risk (Newman et al., 2005; Keren et al., 2008; Maisels et al., 2009b). An hour-specific prebirth hospitalization discharge TSB or TcB level in the high-risk zone (>95%) using the Bhutani nomogram (Bhutani et al., 1999) (Fig. 84.4) is a

• **Fig. 84.4** Nomogram for Designation of Hyperbilirubinemia Risk Based on Hour-Specific Bilirubin Value. (Adapted from Bhutani V, Johnson L, Sivieri EM, et al. Predictive ability of a predischARGE hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. *Pediatrics*. 1999;103:6–14.)

Blinded observations

Neonates with conjunctival icterus (n = 36)

• **Fig. 84.5** Plot of individual neonates (each block = one subject) as a function of total serum bilirubin (mg/dL) and presence (top) or absence (bottom) of conjunctival icterus. Blinded observations of two clinicians; concordant examinations in open bars; the 11 discordant examinations are indicated by hatched bars. (Adapted from Azzuqa A, Watchko JF. Bilirubin concentrations in jaundiced neonates with conjunctival icterus. *J Pediatr*. 2015;167:840–844, with permission.)

major risk factor for severe hyperbilirubinemia (Bhutani et al., 1999; 2000) (Box 84.3), and the clinical factors most predictive of hyperbilirubinemia risk when combined with the risk zone characterization are lower gestational age and exclusive breastfeeding (Newman et al., 2000, 2005; Keren et al., 2008; Maisels et al., 2009a). Coupling predischarge TSB or TcB measurement with gestational age is central to the recommendations for management and follow-up outlined in an update with clarifications to the 2004 AAP clinical practice guideline on the management of hyperbilirubinemia in the newborn infant ≥ 35 weeks' gestation (Maisels et al., 2009a) (see *Clinical Efforts at Kernicterus Prevention* later). Recently published data further suggest that predischarge bilirubin screening is associated with a reduction in the incidence of TSB greater than or equal to 25 mg/dL (428 $\mu\text{mol/L}$) (Eggert et al., 2006; Kuzniewicz et al., 2009; Sgro et al., 2016) possibly by increasing the use of phototherapy (Kuzniewicz et al., 2009).

Clinical Evaluation of Jaundice

Jaundice is the visible manifestation in the skin of elevated serum concentrations of bilirubin. Although most adults are jaundiced when TSB levels exceed 2.0 mg/dL (34 $\mu\text{mol/L}$), neonates characteristically do not appear jaundiced until the TSB exceeds 5.0–7.0 mg/dL (86–120 $\mu\text{mol/L}$). Some degree of jaundice develops in approximately 85% of neonates (Keren et al., 2009), and chemical hyperbilirubinemia, defined as a TSB greater than or equal to 2.0 mg/dL (34 $\mu\text{mol/L}$), is virtually universal in newborns during the first week of life. Jaundice in neonates becomes evident first on the face and progresses in a cephalocaudal fashion, with increasing hyperbilirubinemia, as classically characterized by Kramer (1969). Recent studies, however, suggest that the pattern and intensity of jaundice during the birth hospitalization may not be as reliable an indicator of hyperbilirubinemia degree as previously thought

(Moyer et al., 2000; Keren et al., 2009). Therefore the AAP cautions that “visual estimation of bilirubin levels can lead to errors” (American Academy of Pediatrics, 2004). It is currently recommended that a TcB or TSB measurement complement the clinical assessment for jaundice in every neonate during the birth-hospitalization to assist in hyperbilirubinemia detection and neonatal management (Maisels et al., 2009b).

The absence of jaundice has excellent negative predictive value (99%) for developing a TSB that merits phototherapy (Keren et al., 2009); jaundice limited to the face and upper chest likely predicts a TSB of less than 12.0 mg/dL (Moyer et al., 2000). More recent observations suggest that the presence of conjunctival icterus may be a sign of significant hyperbilirubinemia, often associated with elevations in TSB greater than 14.9 mg/dL [255 $\mu\text{mol/L}$] and greater than 95% on the Bhutani nomogram (Azzuqa and Watchko, 2015) (Fig. 84.5). Others, while confirming a strong correlation with elevated bilirubin levels, also noted conjunctival icterus in neonates at lower bilirubin levels (Maisels et al., 2016). The AAP recommends that parents who detect conjunctival icterus should call their physician, who in turn should evaluate the infant, including a bilirubin measurement.

Kernicterus—Chronic Bilirubin Encephalopathy

Chronic bilirubin encephalopathy (CBE) defines the permanent clinical sequelae of bilirubin toxicity that become evident in the first year of life and is synonymous with the term “kernicterus” (American Academy of Pediatrics, 2004; Shapiro, 2012). These include the extrapyramidal movement disorders of dystonia and/or choreoathetosis, hearing loss caused by auditory neuropathy spectrum disorders, and the eye movement abnormality of paresis of upward gaze (Perlstein, 1960; Shapiro, 2012). The CNS sequelae reflect the regional topography of bilirubin-induced neuronal damage

• **Fig. 84.6** (A) Coronal T2-weighted magnetic resonance image at the level of the basal ganglia in one infant is shown on the left, demonstrating bilateral, symmetric high-intensity globus pallidus (GP) signals (arrows). (B) Deep orange-yellow staining of the GP of the coronal section at postmortem in another neonate. Note unstained putamen (P) and caudate nucleus (Cn). These findings illustrate the selective vulnerability and regional nature of kernicterus and concordance of neuroimaging and neuropathology in this disorder. distinguished by remarkably selective involvement of the globus pallidus, subthalamic nucleus, the CA2–CA3 sectors of the hippocampus, the reticular portion of the substantia nigra, the red nuclei, dentate nuclei and Purkinje cells of the cerebellum, and select brainstem nuclei (Ahdab-Barmada, 1983, 2000; Ahdab-Barmada and Moossy, 1984). Infants with chronic bilirubin encephalopathy often demonstrate abnormal bilateral, symmetric, high-signal intensity on T2-weighted magnetic resonance imaging (MRI) of the globus pallidus and subthalamic nucleus, consistent with the neuropathology of kernicterus (Fig. 84.6) (Shapiro, 2012; Wisnowski et al., 2014).

Originally described in the context of severe hyperbilirubinemia secondary to Rh hemolytic disease (Evans and Polani, 1950; Vaughan et al., 1950), kernicterus has also been reported in other hemolytic conditions (e.g., hereditary spherocytosis and pyruvate kinase deficiency), G6PD deficiency, premature neonates, and in otherwise healthy term ($\geq 37^{0/7}$ weeks) and late-preterm ($34^{0/7}$ – $36^{6/7}$ weeks) gestation breastfed infants without hemolysis (Maisels and Newman, 1995; Bhutani et al., 2004). Population-based kernicterus incidence estimates for term neonates in developed countries range from approximately 0.4–2.7 per 100,000 (Maisels et al., 2012a); higher rates have been reported for (1) preterm newborns (Watchko and Claassen, 1994; Morioka et al., 2016) and (2) infants born in developing countries where kernicterus is a serious endemic problem: e.g., Nigeria, where approximately 3% of neonatal hospital admissions evidence bilirubin encephalopathy (Oguniesi et al., 2007; Zipursky, 2009).

Bilirubin toxicity usually does not become clinically overt until high TSB levels have been established for several hours. Acute bilirubin encephalopathy defines an encephalopathic state during the first days of postnatal life characterized by a constellation of abnormal clinical signs typically progressive in their severity. In term

and late-preterm gestation infants, stupor (lethargy), hypotonia, and poor sucking are seen in the initial phase (Volpe, 2008; Shapiro, 2012). These nonspecific signs are seen in numerous clinical contexts but in a hyperbilirubinemic infant should raise the possibility of early ABE. Clinical signs of intermediate to advanced stages of ABE are increasingly more specific to bilirubin-induced neurotoxicity and herald a marked increased risk for permanent injury (Volpe, 2008; Shapiro, 2012). These include hypertonia often manifested by retrocollis and opisthotonus, fever, and high-pitched cry. Inability to feed and apnea may ensue (Johnson et al., 2009). Infants less than 34 weeks' gestation less frequently show these classic abnormal neuromotor signs. Recurrent apnea and desaturations may be the only clinical manifestations of ABE in preterm infants during the neonatal period, if any appear at all (Amin, 2004; Amin et al., 2014).

Although a preponderance of the literature suggests that once an infant demonstrates advanced signs of ABE, then permanent damage to the CNS has occurred (Jones et al., 1954; Van Praagh, 1961); more recent reports suggest that at least some such infants if treated aggressively may escape unscathed (Harris et al., 2001; Hansen et al., 2009). The latter support the AAP recommendation for immediate exchange transfusion in any infant who is jaundiced and manifests the signs of intermediate to advanced stages of ABE (hypertonia, arching, retrocollis, opisthotonus, fever) even if the TSB is falling (American Academy of Pediatrics, 2004).

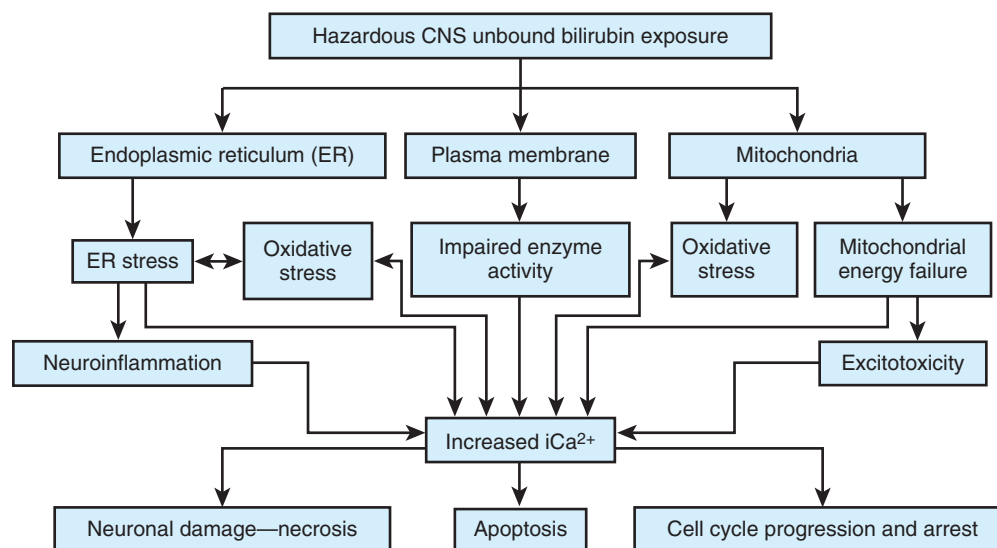

Molecular Pathogenesis

Although no one disputes the neurotoxic potential of bilirubin, the cellular and molecular events attendant to bilirubin-induced neurotoxicity have been only partially characterized, and there is little agreement as to which, from a mechanistic standpoint, may be the most clinically relevant. Fig. 84.7 highlights the multiple

• **Fig. 84.7** Cell Types and Metabolic Processes Affected by Bilirubin in the Central Nervous System.

The main effects of bilirubin on neurons are decreased oxygen consumption and increased release of calcium and caspase 3, resulting in apoptosis. There is also decreased dendritic and axonal arborization. A similar pattern is observed in oligodendrocytes with increased apoptosis, impairment of the redox state (oxidative stress), and reduced synthesis of myelin. Microglia react to toxic injury associated with bilirubin by increased release of proinflammatory cytokines and metalloproteinase activity as cells manifest a phagocytic phenotype. A similar proinflammatory pattern is observed in astrocytes, with enhanced release of glutamate and apoptosis. At the same time, cells may reduce the intracellular concentration of bilirubin either by extruding the pigment through the ABC transporters and/or by increasing the formation of the less toxic products through bilirubin oxidation products (BOXes) and/or cytochrome P450 enzymes (1a1 and 1a2 in particular). These responses are protective, whereas all others result in cell damage; this suggests that once the intracellular concentration of bilirubin exceeds a toxic threshold (still to be defined) the polymorphic metabolic cascade leading to neurotoxicity ensues. *ABCB1*, ATP-binding cassette B1 transporter; *ATP-binding cassette C1 transporter*; *cPARP*, cleaved poly(adenosine diphosphate-ribose) polymerase; *TNF- α* , tumor necrosis factor α ; *TER*, transcellular resistance. • **Fig. 84.8** Schematic of Several Hypothesized Pathophysiologic Mechanism(s) in Bilirubin-Induced Neuronal Injury. Hazardous unbound bilirubin exposure in the central nervous system (CNS) exerts direct effects at level of the plasma membrane, mitochondria, and/or endoplasmic reticulum (ER), leading to ER stress, oxidative stress, impaired enzyme activity, and mitochondrial energy failure, culminating in neuroinflammation, excitotoxicity, and increased intracellular calcium levels (iCa^{2+}). If CNS free bilirubin exposure is of sufficient degree and/or duration than irreversible neuronal damage, i.e., necrosis, and/or cell cycle arrest may ensue.

reported effects of bilirubin on neurons and glia cells (Watchko and Tiribelli, 2013). Bilirubin-induced neuronal cell injury probably reflects the adverse effects of hazardous unbound (“free”) unconjugated bilirubin concentrations on plasma and mitochondrial and/or endoplasmic reticulum membranes (Fig. 84.8) (Watchko, 2006a, 2016; Brites and Brito, 2012; Watchko and Tiribelli, 2013). These membrane perturbations, in turn, precipitate untoward cellular events that culminate in increased intracellular calcium concentrations (iCa^{2+}). Downstream events triggered by increased iCa^{2+} may include the activation of proteolytic enzymes, apoptosis, necrosis, as well as abnormalities of cell cycle progression including cell cycle arrest. Bilirubin-induced excitotoxicity, neuroinflammation, and oxidative stress have all been hypothesized to play important roles in potentiating bilirubin-induced neuronal injury whereas innate cellular characteristics of the CNS may predispose or protect against bilirubin-induced neuronal injury (Watchko and Tiribelli, 2013). Prematurity, hemolysis, and sepsis play key roles in enhancing bilirubin neurotoxicity risk (Watchko, 2004; Watchko et al., 2009).

Preterm Neonates and Low-Bilirubin Kernicterus

Preterm newborns are more vulnerable to kernicterus secondary to CNS immaturity and concurrent adverse clinical conditions that may potentiate bilirubin neurotoxicity. There remains some uncertainty, however, on how to quantify that risk and when to intervene with phototherapy or exchange transfusion in preterm neonates (Hansen, 1996; Maisels, 2000; Maisels and Watchko, 2003). In this regard, low-bilirubin kernicterus, i.e., bilirubin-induced neuronal damage at TSB levels generally thought to be nonhazardous (i.e., those below double volume exchange transfusion thresholds) continue to occur in preterm neonates. The CNS bilirubin exposure, however, is neurotoxic, suggesting either (1) an albumin problem, i.e., an abnormally low serum albumin and/or impaired albumin-bilirubin binding that results in a hazardous unbound unconjugated bilirubin concentration, and/or (2) a

vulnerable neuronal pool resulting from cellular immaturity coupled with antecedent or concurrent insults that potentiate bilirubin neurotoxicity (Govaert et al., 2003; Watchko, Maisels, 2014; Watchko, 2016). Examples of the latter are infection/inflammation, including chorioamnionitis and necrotizing enterocolitis and comorbid CNS injuries including hypoxic-ischemic encephalopathy, intraventricular hemorrhage, and periventricular leukomalacia (Govaert et al., 2003; Watchko 2014; 2016). Oftentimes both an albumin problem and a vulnerable neuronal pool are evident in a given neonate with low bilirubin kernicterus, suggesting this is a two-hit or multihit phenomenon (Watchko 2014, 2016).

Important causes of hypoalbuminemia include leakage of albumin into the extravascular, extracellular interstitial space reported in association with several conditions in sick preterm newborns and significant albumin loss secondary to fetal perinatal hemorrhage. Marked neonatal hypoalbuminemia can be seen in (1) fetal-maternal transfusion, (2) the donor twin in twin-twin transfusion syndrome (TTTS) (Verbeek et al., 2013a) and the twin anemia-polycythemia sequence (TAPS) (Verbeek et al., 2013b), and (3) neonatal anemia associated with malformations of the placenta and cord (Oski, 1982b). Whenever anemia is present in the immediate neonatal period, measurement of the albumin concentration is prudent.

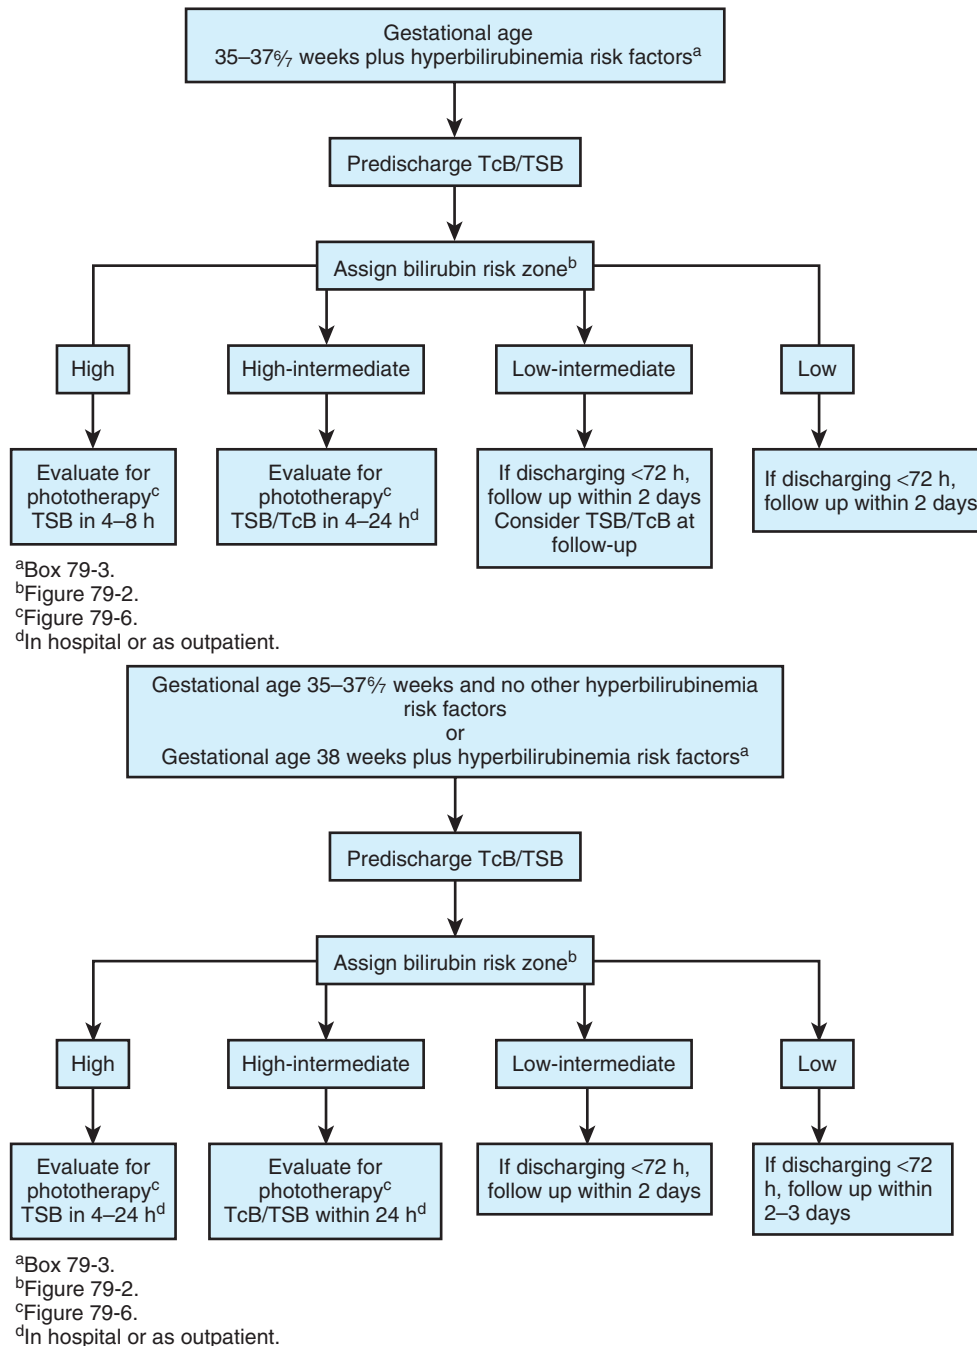

Clinical Efforts at Kernicterus Prevention

The key elements to preventing kernicterus in term and late-preterm neonates are (1) hyperbilirubinemia risk assessment, (2) appropriate and timely birth-hospitalization follow-up, and (3) timely and effective treatment of marked hyperbilirubinemia with phototherapy and/or exchange transfusion. Support of successful breastfeeding is also an important part of hyperbilirubinemia control. A TSB or TcB measured 18–36 hours after birth interpreted according to the infant’s age in hours using the Bhutani hour-specific nomogram (see Fig. 84.4) significantly improves the prediction of subsequent severe hyperbilirubinemia (Newman et al., 2005;

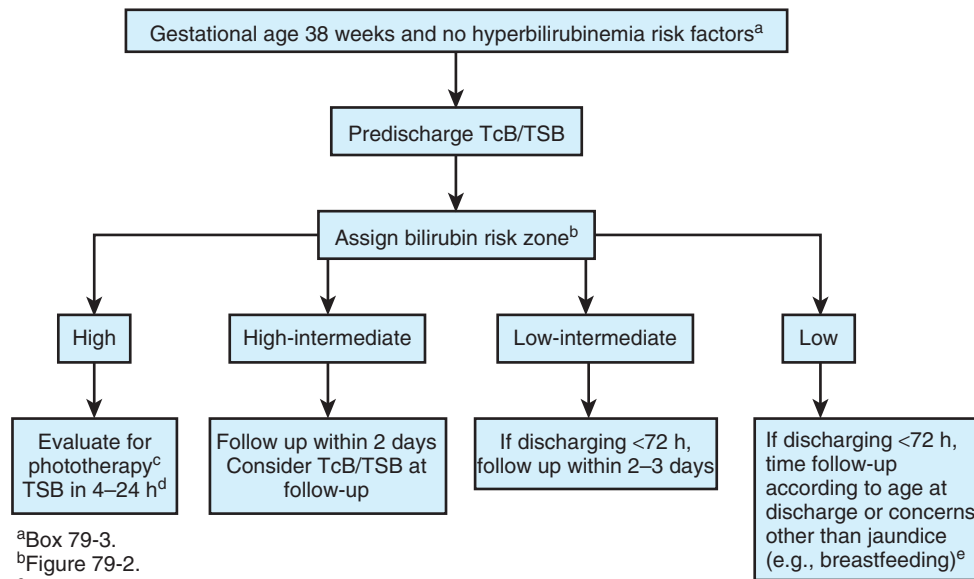

Keren et al., 2008; (Maisels et al., 2009a). As outlined in Fig. 84.9 (Maisels et al., 2009b) the bilirubin risk zone, gestational age at birth, and hyperbilirubinemia risk factors (Box 84.3) combine to assess the risk of subsequent severe hyperbilirubinemia and formulate a plan for birth hospitalization management and timely postbirth hospitalization follow-up (see Fig. 84.9). The AAP has developed a resource kit for hospitals and clinicians to help provide breastfeeding support and manage the jaundiced newborn (www.aap.org/bookstore), and a web-based program developed at Stanford accessible at www.bilitool.org is a practical instrument for plotting hour-specific TSB/TcB measurements.

Treatment Considerations

Phototherapy and exchange transfusion are the mainstays of intervention for neonatal hyperbilirubinemia and current AAP phototherapy, and exchange transfusion treatment thresholds for infants greater than or equal to 35 weeks' gestation are shown in Figs. 84.10–84.11, respectively (American Academy of Pediatrics, 2004). Tables 84.3–84.6 illustrate a range of TSB levels for intervention in varying circumstances for preterm neonates. Phototherapy is generally quite effective and capable of controlling the bilirubin levels in almost all infants, with the exception of the occasional

TABLE 84.3 Guidelines for the Use of Phototherapy and Exchange Transfusion in Low Birth Weight Infants Based on Birthweight^a

| Birthweight (g) | Phototherapy ^c | Total Bilirubin Level (mg/dL [μ mol/L] ^b) Exchange Transfusion ^d |
|-----------------|---------------------------|---|
| ≤1500 | 5–8 (85–140) | 13–16 (220–275) |
| 1500–1999 | 8–12 (140–200) | 16–18 (275–300) |
| 2000–2499 | 11–14 (190–240) | 18–20 (300–340) |

^aNote that these guidelines reflect ranges used in neonatal intensive care units. They cannot take into account all possible situations. Lower bilirubin levels should be used for infants who are sick (e.g., presence of sepsis, acidosis, hypoalbuminemia) or have hemolytic disease.

^bConsider initiating therapy at these levels. Range allows discretion based on clinical conditions or other circumstances. Note that bilirubin levels refer to total serum bilirubin concentrations. Direct reacting or conjugated bilirubin levels should not be subtracted from the total.

^cUsed at these levels and in therapeutic doses, phototherapy should, with few exceptions, eliminate the need for exchange transfusions.

^dLevels for exchange transfusion assume that bilirubin continues to rise or remains at these levels despite intensive phototherapy.

infant with severe hemolysis. Indeed, a rising TSB on phototherapy should raise the concern that the neonate has significant hemolysis, and preparations for exchange should be made if the TSB is rising close to the exchange threshold.

Phototherapy

The most effective phototherapy units deliver output in the blue–green region of the visible spectrum, including the commercially available special blue fluorescent tubes and increasingly light-emitting diode (LED) units (Ennever, 1990; Ebbesen et al., 2016). Special blue fluorescent tubes are labeled F20 T12/BB or

PL52/20W, and they provide much greater irradiance than regular blue tubes (labeled F20T12/B). Special blue tubes and LED units are particularly effective because they provide light with wavelengths that penetrate the skin well and are absorbed maximally by bilirubin (Ennever, 1990; Ebbesen et al., 2016). Phototherapy effectiveness can be further enhanced by increasing the irradiance and the surface area exposed (Maisels, 1996, 2001; Maisels and McDonagh, 2008). Irradiance increases dramatically as the distance between the light source and infant decreases, and this effect is most significant when special blue tubes are used (Maisels and Watchko, 2003). The efficacy of phototherapy is also closely related to the surface area

• **Fig. 84.10** Guidelines for Phototherapy in Hospitalized Infants of Greater Than 35 Weeks' Gestation.

- Use total bilirubin. Do not subtract direct reading or conjugated bilirubin.
- The lines for lower, medium, and higher risk refer to risk for neurotoxicity.
- Risk factors for neurotoxicity—isoimmune hemolytic disease, glucose-6-phosphate dehydrogenase deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis or albumin of less than 3.0 g/dL (if measured).
- For well infants 35–37% weeks can adjust total serum bilirubin (TSB) levels for intervention around the medium-risk line. It is an option to intervene at lower TSB levels for infants closer to 35 weeks and at higher TSB levels for those closer to 37% weeks.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2–3 mg/dL (35–50 mmol/L) below those shown, but home phototherapy should not be used in any infant with risk factors.
- These guidelines refer to the use of intensive phototherapy, which should be used when the TSB exceeds the line indicated for each category. Infants are designated as “higher risk” because of the potential negative effects of the conditions listed on albumin binding of bilirubin (8–10), the blood–brain barrier (11), and the susceptibility of the brain cells to damage by bilirubin (11).
- Intensive phototherapy implies irradiance in the blue-green spectrum (wavelengths of ~430–490 nm) of at least 30 $\mu\text{W}/\text{cm}^2$ per nm (measured at the infant's skin directly below the center of the phototherapy unit) and delivered to as much of the infant's surface area as possible. Note that irradiance measured below the light source center is much greater than that measured at the periphery. Measurements should be made with a spectroradiometer specified by the manufacturer of the phototherapy system.
- If the total serum bilirubin does not decrease or continues to rise in an infant who is receiving intensive phototherapy, this strongly suggests the presence of hemolysis.

(Adapted from American Academy of Pediatrics. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2004;114:297–316.)

of the infant exposed to the phototherapy lights (Maisels and Watchko, 2003). Clinical studies comparing intermittent versus continuous phototherapy in the past have produced conflicting results, but in many circumstances phototherapy does not need to be continuous. As long as the serum bilirubin level is being controlled, phototherapy can be interrupted during feeding or short parental visits.

Recent studies show that phototherapy converts bilirubin to more polar photoisomers quite rapidly that account for about 10% of TSB by 15 minutes of treatment, increasing to 20%–25% of TSB by 2 hours of exposure (Mreihil et al., 2010, 2015). In theory these polar stereoisomers should be less able to cross the blood–brain barrier and enter the CNS (Mreihil et al., 2010, 2015), reducing the risk for neurotoxicity. Preliminary in vitro evidence also suggests that compared with unconjugated bilirubin, bilirubin photoisomers have no direct adverse effect on neuronal cell viability (Jasprova et al., 2016).

Significant complications associated with phototherapy are exceptionally rare. The National Institute of Child Health and Human Development (NICHD) Neonatal Network study on aggressive versus conservative phototherapy for infants with extremely low birth weight (<1000 g), however, merits comment in this regard (Morris et al., 2008). Table 84.7 outlines the aggressive and conservative phototherapy treatment guidelines and exchange transfusion thresholds used in the Network study. Their data suggest that aggressive phototherapy may be preferred for infants of 751–1000 g birthweight because of significant neurodevelopmental benefit, including a reduction in athetosis and severe hearing loss (Morris et al., 2008). However, their findings also raised concerns for aggressive phototherapy use in infants with birthweights of 501–750 g because of a higher mortality rate in that subgroup; i.e., increased mortality may offset any potential neurologic benefits of aggressive treatment in these smallest of infants (Morris et al., 2008). Although it is unclear why phototherapy might increase

• **Fig. 84.11** Guidelines for Exchange Transfusion in Infants of Greater Than 35 Weeks' Gestation.

- Immediate exchange transfusion is recommended if infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, fever, high-pitched cry) or if total serum bilirubin (TSB) is greater than or equal to 5 mg/dL (85 μ mol/L) above these lines.
- The lines for lower, medium, and higher risk refer to risk for neurotoxicity.
- Risk factors for neurotoxicity—isoimmune hemolytic disease, glucose-6-phosphate dehydrogenase (G6PD) deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis.
- Measure serum albumin, and calculate bilirubin/albumin (B/A) ratio (see legend below).
- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- During birth hospitalization, exchange transfusion is recommended if the TSB rises to these levels despite intensive phototherapy. For readmitted infants, if the TSB level is above the exchange level, repeat TSB measurement every 2–3 hours, and consider exchange if the TSB remains above the levels indicated after intensive phototherapy for 6 hours.

The following B/A ratios can be used together with but in not in lieu of the TSB level as an additional factor in determining the need for exchange transfusion.

| Risk Category | B/A RATIO AT WHICH EXCHANGE TRANSFUSION SHOULD BE CONSIDERED | |
|---|--|---|
| | TSB (mg/dL)/ Alb (g/dL) | TSB (μ mol/L)/ Alb (μ mol/L) |
| Infants $\geq 38\frac{6}{7}$ wk | 8.0 | 0.94 |
| Infants $35\frac{6}{7}$ – $36\frac{6}{7}$ wk and well or $\geq 38\frac{6}{7}$ wk if higher risk or isoimmune hemolytic disease or G6PD deficiency | 7.2 | 0.84 |
| Infants $35\frac{6}{7}$ – $37\frac{6}{7}$ wk if higher risk or isoimmune hemolytic disease or G6PD deficiency | 6.8 | 0.80 |

- If the TSB is at or approaching the exchange level, send blood for immediate type and crossmatch. Blood for exchange transfusion is modified whole blood (red cells and plasma) crossmatched against the mother and compatible with the infant.

(Adapted from American Academy of Pediatrics. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics*. 2004;114: 297–316.) Alb, Albumin.

mortality in this birthweight cohort, speculation focuses on greater light penetration deep into subcutaneous tissues via thin gelatinous skin and possible oxidative injury to cell membranes (Maisels et al., 2012b; Vreman et al., 2004).

Perhaps the most noticeable clinical complication encountered during the use of phototherapy is that associated with the presence of direct hyperbilirubinemia or cholestatic jaundice. When infants with direct hyperbilirubinemia are exposed to phototherapy, they may develop a dark, greyish-brown discoloration of the skin, serum, and urine (the “bronze baby syndrome”) (Rubaltelli et al., 1983, 1996). The pathogenesis of this syndrome is unknown but is not

related to copper porphyrins as previously hypothesized (McDonagh, 2011). Although few deleterious consequences of the bronze baby syndrome have been described, there are case reports of infants with this syndrome who developed kernicterus (Clark et al., 1976; Grobler and Mercer, 1997; Maisels, 2000). Impaired binding of bilirubin to albumin has been detected in three infants with this syndrome (Kopelman et al., 1972; Ebbesen, 1982) and in infants with cholestasis (Ebbesen, 1982). If there is a need for phototherapy, the presence of direct hyperbilirubinemia should not be considered a contraindication to its use, particularly in the sick newborn, and, as a rule, the direct serum bilirubin level should not be subtracted

TABLE 84.5 Guidelines for Exchange Transfusion in Low-Birth Weight Infants Based on Total Bilirubin (mg/dL) and Bilirubin/Albumin Ratio (mg/g)^a

| Birthweight (g) | <1250 | 1250–1499 | 1500–1999 | 2000–2499 |

^aExchange transfusion at whichever comes first.^bRisk factors: Apgar less than 3 at 5 minutes; PaO₂ less than 40 mmHg at greater than 2 hours, pH less than 7.15 at greater than 1 hour; birthweight less than 1000 g, hemolysis; clinical or central nervous system deterioration; total protein less than or equal to 4 g/dL or albumin less than or equal to 2.5 g/dL.From Ahlfors CE. Criteria for exchange transfusion in jaundiced newborns. *Pediatrics*. 1994;93:488–494.

from the total bilirubin concentration when decisions are made about initiating phototherapy or an exchange transfusion. In infants who develop the bronze baby syndrome, exchange transfusion should be considered if phototherapy does not lower the TSB. Because of the paucity of data, however, firm recommendations cannot be made. Rarely, purpuric bullous eruptions have also been described in infants with severe cholestatic jaundice receiving phototherapy.

Exchange Transfusion

Exchange transfusion occupies a unique place in the history of neonatal jaundice because it was the first intervention to permit effective control of severe hyperbilirubinemia and prevent kernicterus. In addition to the immediate control of hyperbilirubinemia, an exchange transfusion in immune-mediated hemolytic disease also achieves (1) the removal of antibody-coated red blood cells (a source of “potential” bilirubin), (2) the correction of anemia (if present), and (3) the removal of maternal antibody. A “double volume” exchange refers to an exchange of twice the neonate’s blood volume, or approximately 170–200 mL/kg, and removes approximately 110% of circulating bilirubin (extravascular bilirubin enters the blood during the exchange) but only 25% of total body bilirubin. The exchange transfusion is much less efficient in the removal of total body bilirubin because the majority of the infant’s bilirubin is in the extravascular compartment (Valaes, 1963). Postexchange bilirubin levels are approximately 60% that of preexchange levels, but the rapid (~30 min) reequilibration of bilirubin between the vascular and extravascular compartments produces a rebound of serum bilirubin levels to 70%–80% pre-exchange levels (Brown et al., 1957).

Exchange transfusions are most readily performed via the umbilical vein using a 5- or 8-French umbilical catheter inserted just far enough to obtain free flow of blood (usually no more than the distance between the xiphoid process and umbilicus). The “push-pull” method with a single syringe and special four-way stopcock assembly permits a single operator to complete the procedure (Fig. 84.12; (Watchko, 2000). Given that the efficacy of a double volume exchange is a direct function of the mass of albumin exchanged (Valaes, 1963) the ideal replacement fluid should have both a high plasma volume and a high albumin concentration to optimize the amount of bilirubin-free albumin

TABLE 84.6 Suggested Use of Phototherapy and Exchange Transfusion in Preterm Infants Less Than 35 Weeks Gestational Age

| Gestational Age (wk) | PHOTOTHERAPY | EXCHANGE TRANSFUSION |
|----------------------|---|-------------------------------|
| | Initiate Phototherapy Total Serum Bilirubin (mg/dL) | Total Serum Bilirubin (mg/dL) |
| <28% | 5–6 | 11–14 |
| 28%–29% | 6–8 | 12–14 |
| 30%–31% | 8–10 | 13–16 |
| 32%–33% | 10–12 | 15–18 |
| 34%–34% | 12–14 | 17–19 |

This table reflects the authors’ recommendations for operational or therapeutic total serum albumin (TSB) thresholds—bilirubin levels at, or above which, treatment is likely to do more good than harm. These TSB levels are not based on good evidence and are lower than those suggested in recent UK and Norwegian guidelines.

The wider ranges and overlapping of values in the exchange transfusion column reflect the degree of uncertainty in making these recommendations.

Use the lower range of the listed TSB levels for infants at greater risk for bilirubin toxicity: e.g., (1) lower gestational age; (2) serum albumin levels less than 2.5 g/dL; (3) rapidly rising TSB levels, suggesting hemolytic disease; and (4) those who are clinically unstable. When a decision is being made about the initiation of phototherapy or exchange transfusion, infants are considered to be clinically unstable if they have one or more of the following conditions: (1) blood pH less than 7.15; (2) blood culture positive sepsis in the previous 24 hours; (3) apnea and bradycardia requiring cardiorespiratory resuscitation (bagging and or intubation) during the previous 24 hours; (4) hypotension requiring pressor treatment during the previous 24 hours; and (5) mechanical ventilation at the time of blood sampling.

Recommendations for exchange transfusion apply to infants who are receiving intensive phototherapy to the maximal surface area but whose TSB levels continue to increase to the levels listed.

For all infants, an exchange transfusion is recommended if the infant shows signs of acute bilirubin encephalopathy (hypertonia, arching, retrocollis, opisthotonos, high-pitched cry), although it is recognized that these signs rarely occur in very low birth weight infants.

Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin from the total.

For infants less than or equal to 26 weeks’ gestation, it is an option to use phototherapy prophylactically starting soon after birth.

Use postmenstrual age for phototherapy: e.g., when a 29% week neonate is 7 days old, use the TSB level for 30% weeks.

Discontinue phototherapy when TSB is 1–2 mg/dL below the initiation level for the infant’s postmenstrual age.

Discontinue TSB measurements when TSB is declining and phototherapy is no longer required. Measure the serum albumin level in all infants.

Measure irradiance at regular intervals with an appropriate spectroradiometer.

The increased mortality observed in infants who weigh less than or equal to 1000 g who are receiving phototherapy suggests that it might be prudent to use less intensive levels of irradiance in these infants. In such infants, phototherapy is almost always prophylactic—it is used to prevent a further increase in the TSB, and intensive phototherapy with high irradiance levels usually is not needed. In infants who weigh less than or equal to 1000 g it is reasonable to start phototherapy at lower irradiance levels. If the TSB continues to rise, additional phototherapy should be provided by increasing the surface area exposed (phototherapy above and below the infant, reflecting material around the incubator). If the TSB, nevertheless, continues to rise, the irradiance should be increased by switching to a higher-intensity setting on the device or by bringing the overhead light closer to the infant. Fluorescent and light-emitting diode light sources can be brought closer to the infant, but this cannot be done with halogen or tungsten lamps because of the danger of a burn.

On the other hand, in the first National Institute of Child Health and Human Development (NICHD) trial, irradiance levels were quite low, yet there was a 19% increase in mortality in infants who weighed less than 1000 g who received phototherapy ($P = .112$). One alternative to using lower irradiance is to decrease the length of exposure by using intensive phototherapy for a short period. Another option is to consider intermittent (cyclical) phototherapy. In one recent preliminary study, infants who weighed less than 1000 g who received phototherapy for 15 minutes in the hour had mean peak bilirubin levels (6.5 ± 1.6 mg/dL) that were virtually identical to those receiving continuous phototherapy (6.3 ± 1.3 mg/dL).

TABLE 84.7 Guidelines for Initiating Phototherapy and Exchange Transfusions—NICHD Neonatal Research Network Trial^a

| Birth Weight | AGGRESSIVE MANAGEMENT | | CONSERVATIVE MANAGEMENT | |
|--------------|-----------------------|----------------------|-------------------------|----------------------|
| | Phototherapy Begins | Exchange Transfusion | Phototherapy Begins | Exchange Transfusion |
| 501–750 g | ASAP after enrollment | ≥13.0 mg/dL | ≥8.0 mg/dL | ≥13.0 mg/dL |
| 751–1000 g | ASAP after enrollment | ≥15.0 mg/dL | ≥10.0 mg/dL | ≥15.0 mg/dL |

^aEnrollment expected within the period 12–36 hours after birth, preferably between 12 and 24 hours.

ASAP, As soon as possible; NICHD, National Institute of Child Health and Human Development.

From Morris BH, Oh W, Tyson JE, et al. Aggressive vs. conservative phototherapy for infants with extremely low birth weight. *N Engl J Med*. 2008;359:1885–1896.

• **Fig. 84.12** Special Four-Way Stop Cock Assembly. (1) Male adapter to umbilical venous line (UVC); (2) female adapter to waste bag; and (3) attachment to blood bag and warmer. The stop cock handle points to the port that is open to the syringe, and the stop cock handle is rotated in a clockwise fashion when correctly assembled (e.g., first, withdraw aliquot from infant; second, discard to waste container; third, draw fresh blood from bag, and then fourth, infuse into infant to complete one cycle). (From Watchko JF. Exchange transfusion in the management of neonatal hyperbilirubinemia. In: Maisels MJ, Watchko JF (eds), *Neonatal Jaundice*. Amsterdam: Harwood Academic; 2000, pp. 169–176.)

introduced into the infant's circulation. Accordingly, reconstituted whole blood, i.e., packed red blood cells mixed with fresh frozen plasma to a hematocrit approximating 40%, is preferred. The adult fresh frozen plasma ensures a high albumin concentration and the hematocrit of 40% a high plasma volume. Reconstituted whole blood should be less than 72 hours old and devoid of the offending antigen in the case of immune-mediated hemolytic disease.

Although the risk for graft-versus-host disease following an exchange transfusion is extremely rare, blood for exchange transfusion should be irradiated. The blood should be warmed to body temperature by a blood/fluid warmer. The actual exchange should be performed slowly in aliquots of 5–10 cc/kg body weight with each withdrawal-infusion cycle approximating 3-minute duration (Aranda and Sweet, 1977). Using this approach, a double volume exchange should take approximately 1.5 ± 0.5 hours and avoids deleterious hemodynamic changes (Aranda and Sweet, 1977).

During the exchange, the infant's vital signs should be monitored closely, including electrocardiogram, respiration, oxygen saturation, temperature, and blood pressure. Supplemental calcium gluconate administration during the exchange transfusion has little effect on serum ionized calcium (Maisels et al., 1974; Ellis et al., 1979;

Wieland et al., 1979), and too rapid infusion of calcium may cause bradyarrhythmias or cardiac arrest. If symptomatic hypocalcemia develops, temporary cessation of the procedure will allow recovery toward normal calcium levels as the citrate (which binds calcium) is metabolized by the liver. Postexchange studies should include bilirubin, hemoglobin, platelet count, ionized calcium, serum electrolytes, and serum glucose.

The unintended consequences of exchange transfusion include cardiovascular, hematologic, gastrointestinal, biochemical, and infectious hazards among others (Watchko, 2000). Previously reported overall mortality rates associated with exchange transfusion ranged from 0.3 to 0.95 per 100 procedures (Hovi et al., 1985; Keenan et al., 1985), and significant morbidity (apnea, bradycardia, cyanosis, vasospasm, thrombosis) was observed in 6.7% of infants who received exchange transfusion in the NICHD collaborative phototherapy study (Keenan et al., 1985). These rates, however, may not be generalizable to the current era if, like most procedures, frequency of performance is an important determinant of risk and experience with exchange transfusion is decreasing (Newman and Maisels, 1992). It is quite possible that the mortality (and morbidity) for this now infrequently performed procedure might be higher than previously reported. On the other hand, none of the reports before 1986 included contemporary monitoring capabilities such as pulse oximetry. Jackson (1997) reported a 2% overall mortality rate (2/106) associated with exchange transfusions between 1980 and 1995. There was a 12% risk of serious complications attributable to exchange transfusion in ill infants (Jackson, 1997). Moreover, in infants classified as ill with medical problems in addition to hyperbilirubinemia, the incidence of exchange transfusion-related complications leading to death was 8% (Jackson, 1997). There were no procedure-related deaths in 81 healthy infants (Jackson, 1997). Symptomatic hypocalcemia, bleeding related to thrombocytopenia, catheter-related complications, and apnea-bradycardia requiring resuscitation were common serious morbidities observed in this study, suggesting that exchange transfusion should be performed by experienced individuals in a neonatal intensive care unit with continuous monitoring (including pulse oximetry) prepared to respond to these adverse events. Finally, although the risk is now very low, the risks per tested unit for known transfusion-transmitted viruses in the United States are as follows: for the human immunodeficiency virus, 1:1,467,000; for the hepatitis C virus, 1:1,149,000; and for the hepatitis B virus, 1:282,000 (Carson et al., 2012).

Intravenous Immunoglobulin

Intravenous immunoglobulin (IVIG) inhibits hemolysis in immune-mediated hemolytic disease possibly by blocking Fc receptors

(Hammerman et al., 1996). Although earlier studies and a systematic review suggested that IVIG administration to infants with Rh or ABO hemolytic disease reduces the need for exchange transfusion (Rübo et al., 1992; Dağoglu et al., 1995; Voto et al., 1995; Hammerman et al., 1996; Gottstein and Cooke, 2003), more recent investigations do not (Smits-Wintjens et al., 2011; Santos et al., 2013; Louis et al., 2014). In addition, there have been anecdotal reports of an association of necrotizing enterocolitis with the administration of IVIG (Navarro et al., 2009; Figueras-Aloy et al., 2010; Krishnan and Pathare, 2011; Kara et al., 2013), although this may be product specific (Krishnan and Pathare, 2011, 2012). The AAP recommends the administration of IVIG in immune-mediated hemolytic disease if the TSB is rising despite intensive phototherapy and the TSB level is within 2–3 mg/dL (34–51 $\mu\text{mol/L}$) of the exchange level (American Academy of Pediatrics, 2004).

Congenital Malignant Disorders

TIFFANY FANGTSE LIN, BENJAMIN HUANG, AND ELIZABETH ROBBINS

KEY POINTS

- The spectrum of malignancies in neonates differs from that in children.
- Malignancies in neonates are often associated with a genetic predisposition.
- Neuroblastoma and leukemia are the most common malignancies in neonates.
- Cancer treatment in neonates poses unique challenges, including the likelihood of significant late effects.
- Congenital solid tumors are often diagnosed in utero by ultrasonography.

Neonatal malignancies differ in incidence, clinical behavior, and heritable features from cancers seen in older children. While acute leukemia is the most common malignancy in young children, most neonatal tumors are solid tumors, many of which are detected prenatally during routine ultrasonography. Some childhood malignancies that carry excellent prognoses, such as acute lymphoblastic leukemia (ALL), are often fatal in neonates. In contrast, neuroblastoma, which responds poorly to treatment in older children, can spontaneously regress in newborns.

Treatment of cancer in the neonatal period presents special challenges. Among these are differences in drug metabolism in newborns, the sensitivity of rapidly growing normal tissues to chemotherapeutic agents and radiation, and the increased possibility of late effects, including neurocognitive sequelae, impaired reproductive capacity, growth disturbances, and secondary malignancies. The epidemiology, etiology, and diagnosis of neonatal malignancy are reviewed here, followed by a discussion of commonly encountered malignancies.

Epidemiology, Etiology, and Diagnosis of Neonatal Malignancy

Epidemiology: Incidence and Mortality

Neonatal tumors are rare, with an incidence of 1 per 27,500 live births in the United States; they compose 2% of childhood malignancies (Moore et al., 2003). Although trend analyses suggest that the incidence of malignancy in the pediatric population may

be increasing (Linabery and Ross, 2008), a number of factors affect incidence rates, including improvements in molecular methods of diagnosis, changes in population characteristics, screening fetal ultrasonography practices, and case ascertainment by cancer registries (Spector and Linabery, 2009).

The most common malignancy in infants is neuroblastoma, followed by leukemia, central nervous system (CNS) tumors, retinoblastoma, and germ cell tumors (Linabery and Ross, 2008). Female and male infants have similar cancer incidence rates, but white infants have significantly higher rates than those reported in African-American infants for all histologic types. The distribution of the major types of cancers in newborns, infants, and children is depicted in Table 85.1. Incidence rates for the most common types of malignancy in infants are shown in Table 85.2.

The mortality rates for infants with cancer exceed those for older children, even among identical diseases (Ries et al., 1999). Despite cure rates exceeding 85% for children older than 1 year with a diagnosis of ALL, newborns with ALL have cure rates of less than 50% (Pieters et al., 2007). Poorer survival patterns for infants are also seen with rhabdomyosarcoma and CNS tumors, including primitive neuroectodermal tumor (PNET), atypical teratoid/rhabdoid tumor (ATRT), and ependymoma (Ries et al., 1999). Two notable exceptions are neuroblastoma, for which the 5-year survival rate in newborns with disseminated disease is more than 90%, and infantile fibrosarcoma, for which cure rates in newborns often exceed those achieved in older children or adults.

Etiology

Genetic Predisposition Syndromes and Congenital Defects

The cause of cancer in children is multifactorial, involving both genetic and environmental factors. However, in neonates, predisposing genetic factors more often play an important role. An acquired or inherited abnormality of a cancer-predisposing gene that is critical during embryogenesis underlies some cases of neonatal cancer, and the malignant transformation of normal cells results from the activation or suppression of these cancer-predisposing genes. The retinoblastoma gene at 13q is an example of a constitutional chromosomal abnormality that results in a high risk of malignancy.

A number of defined hereditary conditions and genetic defects are associated with an increased incidence of specific neoplasms; these are listed in Table 85.3. Except for retinoblastoma,

TABLE 85.1 Distribution of the Major Types of Cancer in Newborns, Infants, and Children

| Malignancy | Newborns Younger Than 30 Days (%) | Infants Younger Than 1 Year (%) | Children Younger Than 15 Years (%) |
|-------------------------------------|---|---------------------------------------|--|
| Leukemia | 13 | 14 | 31 |
| Central nervous system tumors | 3 | 15 | 18 |
| Neuroblastoma | 54 | 27 | 8 |
| Lymphoma | 0.3 | 1 | 14 |
| Renal tumors | 13 | 11 | 6 |
| Sarcoma | 11 | 5 | 11 |

EBV, Epstein–Barr virus; JMML, juvenile myelomonocytic leukemia; WAGR, Wilms tumors, aniridia, genitourinary abnormalities, mental retardation.

Data from Orbach D, Sarnacki S, Brisse HJ, et al. Neonatal cancer. *Lancet Oncol.* 2013;14:e609–e620 and Jackson EM, Shaikh TH, Gururangan S, et al. High-density single nucleotide polymorphism array analysis in patients with germline deletions of 22q11.2 and malignant rhabdoid tumor. *Hum Genet.* 2007;122:117–127.

hepatoblastoma, and Wilms tumor, the neoplasms associated with these syndromes seldom manifest themselves in the neonatal period, but the associated abnormalities may be recognized early, allowing regular screening. A lack of a family history should not dissuade the clinician from investigating these syndromes, as both spontaneous germline mutations and parental mosaicism occur. The genetic defect in many of these neoplasms has been identified. For example, the *NF1* gene, located at 17q11.2, encodes a protein, neurofibromin, that normally acts as a guanosine triphosphatase-activating protein that downregulates the Ras signaling pathway. Children with neurofibromatosis1 (NF1) are at increased risk of developing juvenile myelomonocytic leukemia (JMML), a rare but aggressive myeloproliferative neoplasm that is currently only cured with hematopoietic stem transplant (Niemeyer and Kratz, 2008). In children with NF1 and JMML, the hematopoietic cells display loss of the wild-type *NF1* gene and duplication of the mutant allele, thus

resulting in the complete loss of the normal neurofibromin protein in the leukemia cells (Stephens et al., 2006). This promotes cell growth because there is no functional “off” switch.

A large number of childhood tumors occur in association with congenital defects. For instance, Down syndrome has an increased association with both leukemia and transient myeloproliferative disorders. Children with congenital aniridia have an increased incidence of Wilms tumor. While aniridia is found in only 1 in 75,000 persons, it is found in as many as 1 in 75 children with Wilms tumor. Children with abnormalities of the Wilms tumor 1 gene (*WT1*), located at chromosome band 11p13, also have an increased risk of developing Wilms tumor (Scott et al., 2006). Most individuals with constitutional *WT1* defects have associated phenotypic syndromes that include combinations of genitourinary abnormalities, renal dysfunction, and mental retardation. Beckwith–Wiedemann syndrome (BWS) and hemihypertrophy syndromes

are associated with several neoplasms. This syndrome is typified by macroglossia, gigantism, and abdominal wall defects; patients may also have visceromegaly, flame nevus, neonatal hypoglycemia, microcephaly, and retardation (Scott et al., 2006). Approximately 8% of infants with either the complete syndrome or the partial syndrome develop neoplasms, including Wilms tumor, adrenal cortical carcinoma, and hepatoblastoma—tumors of the same organs in which visceromegaly develops. Also reported are rhabdomyosarcoma, neuroblastoma, ganglioneuroma, and adenomas and hamartomas. BWS is linked with abnormalities of 11p15; this is the location of the insulin-like growth factor II gene (*IGF2*) and the tumor suppressor gene *H19* (Rahman, 2005).

Transplacental Tumor Passage

An exceedingly rare cause of cancer in neonates and infants is the transplacental passage of tumor cells from the mother. Rare cases of transplacentally transmitted cancer have been reported (Tolar et al., 2002). The malignancies transmitted include leukemia, melanoma, lymphoma, hepatic carcinoma, and lung cancer. The diagnosis of transplacentally acquired neoplasm usually occurs at birth but has been reported as late as age 8 months. The frequency of concurrent maternal malignancy in pregnant women is estimated at 1 per 1000 pregnancies (Pavlidis, 2002; Maruko et al., 2004), and alternative treatment plans or delays in treatment are options for pregnant women. That transplacental transmission is so rare is attributed to the protective function of the placenta.

Twin-to-Twin Transmission

The risk of development of leukemia is increased in a monozygotic twin. If one monozygotic twin has leukemia, the cotwin has an approximately 25% chance of developing leukemia, usually within weeks or months of the diagnosis in the sibling. A dizygotic twin on the other hand has only a slightly increased risk of developing leukemia. This increased incidence is likely due to in utero twin-to-twin transmission of a preleukemic clone rather than the simultaneous development of a shared germline mutation facilitating the later development of leukemia.

Environmental Factors

Environmental factors are probably less important in the development of neonatal cancer compared with their role in the development of cancer in older children and adults. Nonetheless, there is evidence that environmental influences, including radiation exposure, maternal medication use, and various environmental exposures, may affect the incidence of neonatal cancer (Moore et al., 2003).

Exposure to ionizing radiation during pregnancy is known to increase the risk of a number of tumors, including acute leukemia, in exposed offspring. There appears to be a dose–response relationship between the dose of ionizing radiation received by the fetus in utero and the subsequent development of cancer in childhood, with doses on the order of 10 milliGray sufficient to produce an increase in risk. Mixed evidence comes from atomic bomb survivors who were exposed to radiation in utero and from studies that followed Doll and Wakeford's study. Maternal exposure to ionizing radiation should be used sparingly and only for diagnostic purposes if required (Brent, 2014).

Maternal exposure to some drugs during pregnancy has been associated with the subsequent development of cancer in offspring. Maternal use of diethylstilbestrol has been strongly associated with the development of clear cell adenocarcinoma of the vagina and cervix in daughters born from those pregnancies. Some substances and exposures known to be teratogenic may also be carcinogenic

to offspring. Excessive maternal alcohol consumption may be linked to an increased risk of developing cancer in the newborn period, particularly acute myeloid leukemia (AML). The use of fertility drugs does not appear to increase the risk of cancer in the exposed offspring (Basatemur and Sutcliffe, 2008).

Environmental exposures of the mother or father to hydrocarbons, dyes, and other chemicals and solvents may be related to the development of neonatal tumors, but there is only a weak association for most of the risk factors identified (McCall et al., 2005). The association of neoplasms with other environmental factors, such as maternal use of tobacco, has not been conclusively proven (Momen et al., 2016).

Diagnosis and Evaluation

The diagnostic evaluation of a newborn suspected of having cancer is guided by the signs and symptoms of the disease. Symptoms of malignancy in neonates can be nonspecific, such as irritability, poor feeding, failure to thrive, and fever. Table 85.4 lists clinical features associated with the more common malignancies found in the neonatal period. Most neonatal tumors present as a mass at birth; often the mass has previously been identified by prenatal ultrasonography. Postnatal imaging with magnetic resonance imaging (MRI) is usually required to better delineate the lesion.

Laboratory and pathologic evaluations should be directed at making the diagnosis efficiently, sparing the newborn unnecessary procedures that could result in acute and chronic morbidity. Routine laboratory studies, including a complete blood count (CBC) and liver and renal function tests, should be performed. Urine catecholamine excretion should be measured when neuroblastoma is being considered. Serum alpha fetoprotein (AFP) and beta human chorionic gonadotropin (β -hCG) levels should be measured in infants suspected of having a germ cell tumor or teratoma; these can serve as tumor markers, although the normally elevated levels in infancy can complicate the interpretation of these values (Wu et al., 1981). A pediatric oncologist should be consulted. Surgeons and pathologists should submit biopsy tissue for histologic examination, immunoperoxidase staining, flow cytometry, cytogenetic analysis, and tumor banking.

Specific Neoplasms

Neuroblastoma

Overview

Neuroblastoma is the most common malignant tumor of infancy. It is of embryonal origin, derived from neural crest cells that have committed to the sympathoadrenal lines. The tumor can present in utero, in infancy, and in childhood; the age of presentation significantly affects the prognosis and treatment plans. Because, in part, of improvements in prenatal ultrasonography, neuroblastoma is now diagnosed in more children; neuroblastoma is diagnosed in approximately 100 children per year in North America prenatally or at age less than 3 months (Nuchtern, 2006).

Etiology

Neuroblastoma can be associated with genetic disorders but does not have a single cause. The incidence is increased in patients with Turner syndrome, Noonan syndrome (in 50% of Noonan syndrome patients the *PTPN11* gene is mutated, which is associated with an increased risk of leukemia and neuroblastoma), and Costello

TABLE 85.4 Differential Diagnosis of Malignant and Nonmalignant Conditions in Infancy

| Feature | Malignancy | Nonmalignant Condition |
|---|--|---|

syndrome. While *NF1* mutations have been detected in neuroblastoma cell lines, patients with germline *NF1* mutations do not have a predisposition to neuroblastoma. In BWS and other overgrowth disorders, neuroblastoma is more common, and abdominal ultrasonography is recommended quarterly until age 8 years for early detection. Congenital central hypoventilation syndrome (specifically the *PHOX2B* mutation) and Hirschsprung disease are associated with increased risk of neuroblastoma and ganglioneuroblastoma. There are cases of familial neuroblastoma; in 80% of these cases the anaplastic lymphoma kinase receptor has been found to be mutated although there are no phenotypic abnormalities (Janoueix-Lerosey et al., 2008). In addition to germline mutations in the familial cases, somatic *ALK* mutations are found in up to 12% of sporadic neuroblastoma tumors (Mossé et al., 2008).

Presentation

In children, symptoms of neuroblastoma are often due to a mass effect in the compartment of tumor origin. Among all pediatric neuroblastoma cases, two-thirds of cases occur within the abdominal cavity; most of these occur in the adrenal glands. Abdominal distention is a common initial presentation. Neuroblastoma can occur anywhere along the sympathetic chain, however, and is sometimes incidentally found on chest X-rays. Neuroblastoma in the posterior mediastinum can present as bronchial obstruction. Neuroblastoma arising in the sympathetic paraspinal ganglia may invade the neural foramina, causing spinal cord compression with associated neurologic symptoms. Tumor cells can also rarely be found circulating on review of the peripheral blood smear (Fig. 85.1).

In the newborn, neuroblastoma presents commonly as an asymptomatic adrenal mass found on routine ultrasonography, but it most often manifests itself as stage 4S (or stage MS) neuroblastoma with hepatomegaly, seen in 65% of cases, followed by subcutaneous metastases, seen in 32% of cases. This metastatic pattern is different from that seen in older infants and children (Table 85.5). Metastases to the lungs, bones, skull, and orbit are rare in the newborn, although clumps of tumor cells are often found in the bone marrow. In the newborn the primary site of disease often cannot be identified or may be a small adrenal primary tumor. Liver involvement can cause massive hepatomegaly, which can be a cause of dystocia during vaginal delivery. This massive involvement can also cause abdominal distention, coagulopathy, heart failure, and life-threatening respiratory distress (Fig. 85.2).

TABLE 85.5 Sites of Metastatic Disease at Diagnosis for 81 Patients With Stage 4S Neuroblastoma, 133 Patients With Stage 4 Neuroblastoma Younger Than 1 Year, and 434 Patients With Stage 4 Neuroblastoma 1 Year or Older

| Sites of Metastases | Stage 4S | Stage 4 <1 year | Stage 4 ≥1 year | Total (%) |

^aSignificant difference between the proportion of patients with stage 4S neuroblastoma with the site and the proportion of patients with stage 4 neuroblastoma younger than 1 year with the site ($P < .01$), only for those sites which are included in the definition of stage 4S neuroblastoma.

^bSignificant difference between the proportion of patients with stage 4 neuroblastoma younger than 1 year with the site and the proportion of patients with stage 4 neuroblastoma 1 year or older with the site ($P < .02$).

From DuBois S, Kalika Y, Lukens J, et al. Metastatic sites in stage IV and IVA neuroblastoma correlate with age, tumor biology, and survival. *J Pediatr Hematol Oncol*. 1999;21:181–189.

Subcutaneous skin nodules are typically bluish, and palpation of the nodules leads to transient erythema followed by blanching, presumably because of the vasoconstriction caused by the release of catecholamines from the tumor cell.

The neoplasm may also arise in the neck or pelvis. Involvement of the stellate ganglion may result in Horner syndrome, which includes ptosis of the upper eyelid, slight elevation of the lower eyelid, meiosis, narrowing of the palpebral fissure, anhidrosis, and enophthalmos (Fig. 85.3). Neuroblastoma arising from the paravertebral sympathetic ganglion has a tendency to grow into the intervertebral foramina, causing spinal cord compression and resultant paralysis. Careful periodic neurologic evaluation should be performed in a child with neuroblastoma in this region to evaluate the child for the onset of cord compression, which may necessitate emergency intervention with chemotherapy, surgery, or irradiation.

Unusual Presentations

Intractable diarrhea can be the sole presenting manifestation of neuroblastoma. Secretion of vasoactive intestinal peptide by the tumor has been postulated to be the cause of the diarrhea, which resolves following surgical removal of the tumor (Bourdeaut et al., 2009).

• **Fig. 85.2** Stage 4S neuroblastoma causing abdominal distention and respiratory distress secondary to hepatic infiltration.

• **Fig. 85.3** Horner syndrome in an infant with neuroblastoma arising from the left cervical sympathetic ganglion.

Opsoclonus and *myoclonus* (“dancing eyes, dancing feet”) are associated with neuroblastoma, although this presentation is only rarely seen in the neonatal period (Rudnick et al., 2001). Patients have rapid multidirectional eye movements (opsoclonus), myoclonus, and truncal ataxia (OMA) in the absence of increased intracranial pressure. The condition may be due to an autoimmune reaction, as the presence of antineuronal antibodies has been shown to be significantly more common in children with neuroblastoma and OMA than in case-controlled neuroblastoma patients (Antunes et al., 2000). Removal of the tumor usually results in a decrease in neurologic signs and symptoms, but the use of steroids is frequently required for complete resolution. In general, the prognosis

for survival of children with opsomyoclonus is excellent, although long-term neurologic deficits and learning delays are common and can be quite debilitating.

Maternal symptoms such as sweating, pallor, headaches, palpitations, hypertension, and tingling in the feet and hands during the eighth and ninth months of pregnancy may rarely be a sign of neuroblastoma in the fetus. The symptoms, which disappear after birth, are likely caused by fetal catecholamines entering the maternal circulation. Newborns with neuroblastoma whose mothers have experienced these symptoms typically receive a diagnosis of neuroblastoma shortly after birth or during the first few months of life.

Erythroblastosis with hepatosplenomegaly, severe jaundice, and an increase in the number of nucleated red blood cells is occasionally seen in newborns with neuroblastoma. Congenital neuroblastoma with metastases to the liver and placenta can be clinically indistinguishable from hydrops fetalis.

Catecholamine Secretion

A hallmark of neuroblastoma cells is the ability to store and secrete catecholamines. Patients with neuroblastoma usually have elevated urinary levels of norepinephrine as well as its biochemical precursors and their metabolites. More than 90% of patients have an elevated urinary excretion of vanillylmandelic acid (VMA) or homovanillic acid (HVA) or both. VMA and HVA determinations can be made on random urine samples when values are normalized for creatinine concentration. In the occasional case with no elevation of catecholamine levels, a 24-hour urine collection is necessary. Catecholamine secretion can be used not only as a diagnostic aid but also as a means to assess the response to therapy and to detect tumor recurrence. Thus urine catecholamine levels should be measured before surgical removal of the tumor or before initiation of therapy.

Diagnosis

Clinical evaluation should include a physical examination with particular attention paid to detecting an abdominal mass, hepatomegaly, lymphadenopathy, Horner syndrome, and skin lesions; a baseline neurologic examination is also performed. Laboratory evaluation should include a CBC, tests for urine levels of VMA and HVA, and tests for serum ferritin and lactate dehydrogenase. While the initial imaging study in an infant is often abdominal ultrasonography, additional imaging to better delineate the tumor and to evaluate the infant for metastatic disease is needed; this should include computed tomography (CT) or MRI of the primary lesion. MRI of the spine should be performed for paraspinal and posterior mediastinal lesions. An [^{123}I]metaiodobenzylguanidine (MIBG) scan is particularly important for diagnosis and follow-up. MIBG, a norepinephrine analogue specifically taken up by neuroblastoma in bone and soft tissue, serves as a sensitive modality (90% sensitive) for disease localization (Matthay et al., 2010). Bilateral bone marrow aspiration (along with bilateral bone marrow biopsy in patients older than 6 months) is also part of the initial evaluation.

Histologic evidence provides confirmation of the diagnosis of neuroblastoma. Tissue may be obtained from a primary lesion or a metastatic site. Because tumor-specific biologic information plays a critical role in risk classification and treatment recommendations, obtaining adequate tissue for biologic studies is essential.

Pathologic Classification

Neuroblastoma is made up of small round blue cells that are uniformly sized and contain dense, hyperchromatic nuclei and

TABLE 85.6 Features That Affect Prognosis in Neuroblastoma

| Feature | Favorable | Unfavorable |
|------------------------|--|---|
| Age at diagnosis | <18 months | >18 months |
| INRG stage | L1, L2, MS | M |
| <i>MYCN</i> status | Nonamplified | Amplified |
| Histologic appearance | Ganglioneuroma, ganglioneuroma maturing, ganglioneuroblastoma intermixed | Ganglioneuroblastoma nodular or neuroblastoma |
| DNA ploidy (DNA index) | >1 or <1 | 1 |
| Allelic status of 11q | Normal | 11q deletion or LOH at 11q or any segmental chromosome loss |

INRG, International Neuroblastoma Risk Group; LOH, loss of heterozygosity.

scattered cytoplasm with stroma around it. Immunohistochemistry is positive for neurofilament protein, synaptophysin, neuron-specific enolase, ganglioside GD2, and chromogranin A, which distinguishes it from the other small round blue cell tumors of childhood. The histopathologic appearance of neuroblastoma ranges from undifferentiated neuroblasts, to more mature ganglioneuroblastoma, to fully differentiated and benign ganglioneuroma. The most widely used morphologic classification system is based on the system proposed by Shimada et al. (1984) in which tumors are classified as favorable or unfavorable. It is based on the amount of stroma, degree of neuroblastic differentiation, and the mitosis–karyorrhexis index. Additional classification systems exist; the International Neuroblastoma Pathology Classification separates neuroblastoma into four categories: (1) neuroblastoma that is undifferentiated, poorly differentiated (<5% exhibiting differentiation), or differentiating (>5%); (2) ganglioneuroblastoma, intermixed; (3) ganglioneuroblastoma, nodular; and (4) ganglioneuroma.

Genetic Prognostic Factors: Tumor Biology

In addition to clinical factors and histology, a number of biologic factors have been shown to correlate with prognosis (Table 85.6). Genomic data currently used in risk classification schemes include the status of the *MYCN* oncogene, tumor cell DNA content (ploidy), and the allelic status of chromosome arms 1p, 11q, 14q, and 17q (Ambros et al., 2009). More recently, it has been found that any segmental chromosomal abnormality indicates a less favorable outcome.

Amplification of the *MYCN* oncogene is present in 16% of primary neuroblastomas and has been shown to correlate with poor prognosis independent of age, stage, and other genetic alterations (Thompson et al., 2016). Patients with stage 1, 2, or 4S disease demonstrate *MYCN* amplification only rarely; when present, it has been associated with rapid disease progression in these normally favorable stages. In a Children's Cancer Group study of stage 4 neuroblastoma in infants, the progression-free survival rate after 3 years was less than 10% in infants with tumors that demonstrated *MYCN* amplification, compared with 93% for those with single-copy tumors.

Total cellular DNA content also predicts response to therapy in infants with neuroblastoma (Look et al., 1991). Diploid DNA content is an unfavorable prognostic factor, particularly in infants younger than 12 months. Infants with hyperdiploid tumors have a significantly better response to therapy than those with diploid tumors. Diploidy often correlates with tumor *MYCN* amplification, although in rare cases of hyperdiploidy with *MYCN* amplification, the *MYCN* amplification portends an unfavorable outcome.

Tumor karyotype also influences outcome. Common genomic aberrations found in neuroblastoma include deletion at chromosomal region 1p36.3 or 11q23, deletion of 14q32, and unbalanced gain of the long arm of chromosome 17 (17q21 to 17qter) (Ambros et al., 2009). Loss of heterozygosity (LOH) of 1p occurs in up to 36% of primary tumors, and LOH at 11q23 is seen in 44% of primary neuroblastomas (Guo et al., 1999). Both are associated with poor outcomes, older age at presentation, and advanced-stage disease. Gain of 17q occurs in 60% of neuroblastomas and is associated with metastatic disease and unfavorable prognosis. Comprehensive genome-wide approaches such as comparative genomic hybridization are becoming increasingly useful in refining the prognostic accuracy of chromosomal alterations (Schleiermacher et al., 2007).

Staging

Neuroblastoma has traditionally been staged according to the International Neuroblastoma Staging System (INSS). Staging is based on age, disease site(s), and degree of surgical resection. New guidelines for a pretreatment risk classification system have been developed by the International Neuroblastoma Risk Group (INRG) Task Force and are being used in addition to the INSS summarized in Table 85.7 (Monclair et al., 2009); this system is undergoing evaluation in risk-based clinical trials. INRG stages include L1, localized tumor not involving vital structures (corresponds to INSS stages 1 and 2); L2, locoregional tumor with one or more image-defined risk factors (corresponds to INSS stage 3); M, metastatic disease (corresponds to INSS stage 4); and MS, metastatic disease in children younger than 18 months with metastases confined to skin, liver, and/or bone marrow (corresponds to INSS stage 4S). Two important differences in the INRG system compared with the INSS are that it is a radiologic rather than a surgical staging system and that the upper age limit for stage MS has been extended from 12 to 18 months.

TABLE 85.7 International Neuroblastoma Risk Group Staging System

| Stage | Definition |
|-------|---|
| L1 | Localized tumor not involving vital structures as defined by the list of image-defined risk factors ^a and confined to one body compartment |
| L2 | Locoregional tumor with the presence of one of more image-defined risk factors ^a |
| M | Distant metastatic disease (except stage MS) |
| MS | Metastatic disease in children younger than 18 months with metastases confined to the skin, liver, and/or bone marrow |

^aImage-defined risk factors are specific to each body compartment. For example, risk factors within the neck include tumor encasing the carotid and/or vertebral artery and/or internal jugular vein, tumor extending to the base of the skull, or tumor compressing the trachea. Data from Monclair T, Brodeur GM, Ambros PF, et al. The International Neuroblastoma Risk Group (INRG) staging system: an INRG Task Force report. *J Clin Oncol*. 2009;27:298–303.

Stage 4S (MS) comprises a unique group of patients with disseminated disease but a good prognosis. This combination occurs exclusively in infants. In this special group of patients, typical findings include a small primary tumor that does not cross the midline and remote spread involving the liver, skin, or bone marrow (<15% of marrow replacement by tumor), without radiographic evidence of skeletal metastases. There is lack of *MYCN* oncogene amplification in most INSS stage 4S tumors, in contrast to INSS stage 4 tumors (Seeger et al., 1985). Infants with INSS stage 4S disease have a very good prognosis despite having disseminated disease (5-year survival rate >90%); spontaneous regression occurs without cytotoxic therapy in approximately 50% of cases (Nickerson et al., 2000; Hero et al., 2008; Taggart et al., 2011).

Treatment

Treatment modalities for neuroblastoma include observation alone, surgery, chemotherapy, and radiation therapy or a combination of these. Patients with INSS stage 1 and INSS stage 2 neuroblastoma have a 96%–100% survival rate with surgery alone (Strother et al., 2012). Isolated adrenal masses, the more common presentation among infants with neuroblastoma diagnosed prenatally, can be monitored closely for spontaneous regression if a tumor diameter meets the size criteria and if urine VMA and HVA levels are decreasing (Nuchtern et al., 2012). Infants with INSS stage 3 and INSS stage 4 disease have a poorer survival, even with aggressive chemotherapy, although the outcome, with better than 70% surviving overall, is far better than the survival rate of 10%–20% reported for older children with disease of these stages (Schmidt et al., 2000).

The unpredictable course of neuroblastoma, with its occasional spontaneous maturation or regression, not only makes this tumor unusual but also requires careful assessment of clinical and biologic risk factors in planning therapy. The type and intensity of treatment are determined by identification of infants with relatively good, intermediate, and poor prognoses on the basis of stage, international pathology classification, Shimada histologic classification, ploidy, segmental chromosomal abnormalities, and *MYCN* amplification. Patients who have localized disease (L1 or L2) without amplification of *MYCN* have an excellent prognosis, and such patients should undergo surgical resection or partial resection, but they likely will not derive any additional benefits from postoperative chemotherapy or radiation therapy. An exception to this rule is in the case of spinal cord compression, in which prompt decompression with chemotherapy, laminectomy, or local irradiation may be used to preserve function. There is an increasing trend to use chemotherapy first, given the exquisite sensitivity of the tumor to chemotherapeutic agents, but a rapid deterioration in neurologic function should prompt alternative interventions. A neurosurgeon should be consulted early in the diagnosis. The combination of extensive laminectomy with postoperative irradiation should be avoided because later spinal deformity is almost inevitable. Infants with stage 3 and stage 4 disease are usually treated with a combination of chemotherapy and local surgery, with radiation therapy given only as necessary to eradicate residual disease. The active drugs that are most commonly used include cisplatin or carboplatin, etoposide, doxorubicin, cyclophosphamide, and vincristine. Infants with stage 4 disease with amplification of the *MYCN* oncogene have a very unfavorable prognosis; standard chemotherapy regimens are not sufficient for cure. In these high-risk patients, intensive chemotherapy followed by myeloablative therapy with stem cell support may offer additional benefit (Canete et al., 2009). In addition, the use of the differentiation agent isotretinoin and the

anti-GD2 antibody ch14.18 has been shown to improve outcome in patients with advanced-stage, high-risk neuroblastoma (Matthay et al., 2009; Yu et al., 2010).

Infants with INSS stage 4S disease have a highly favorable prognosis and may require minimal or no therapy. Because many patients undergo spontaneous regression, therapy should be directed toward supportive care, with use of chemotherapy and surgery restricted to relieving symptoms (De Bernardi et al., 2009). The main cause of death in these patients is massive hepatic involvement resulting in respiratory insufficiency or compromise of renal or gastrointestinal function. Symptomatic patients are treated with chemotherapy. When there is a risk of organ impairment due to tumor bulk not responding to initial chemotherapy, low-dose radiotherapy can be administered (450 centiGray given in three fractions; in some cases not all three fractions are needed) (Nickerson et al., 2000; Taggart et al., 2011).

Prenatal Diagnosis

Neuroblastoma is increasingly being detected prenatally by screening ultrasonography. Newborns with adrenal or other mass lesions detected prenatally should be evaluated by urine catecholamine levels (although this has a low specificity) and follow-up ultrasonography. Careful observation may be adequate for infants with localized tumors, which frequently regress.

Newborn Screening

Newborn screening for neuroblastoma by the measurement of urine catecholamine levels has been studied in Japan and a number of other countries (Hiyama et al., 2008). It was hoped that early diagnosis of neuroblastoma would reduce the frequency of cases with poor prognosis from advanced-stage disease. Screening, however, has had a mixed impact on survival; neuroblastomas detected by screening almost always have favorable biologic features (Schilling et al., 2002), although screening in infants in Japan was shown to reduce overall mortality (Hisahige, 2014). Routine screening of infants for neuroblastoma is not currently recommended.

Congenital Leukemia

Epidemiology

Although leukemia is the second most common malignancy in infants, congenital leukemia, defined as leukemia diagnosed in the first 4 weeks of life, is quite rare. The incidence of leukemia in the first 3 months is approximately five cases per million (Bajwa et al., 2004). Two-thirds of congenital leukemia cases are classified as AML, in contrast to older infants and children, in whom ALL predominates. Congenital leukemia is associated with a high mortality with an overall survival rate at 24 months of only 20% (Van der Linden et al., 2009), which is due to the aggressive biology of these leukemias and age-related treatment complications.

The cause of leukemia is unclear. In infants and older children a number of factors are associated with the development of leukemia; these include genetic factors, environmental influences, and immunodeficiencies. Genetic epidemiologic studies of infant leukemia indicate that most, if not all, cases are initiated in utero and involve acquired, noninherited genetic rearrangements; chromosome band 11q23 (*MLL* rearrangement) is frequently involved. Leukemia-associated gene rearrangements have been retrospectively identified in archived newborn screen blood spots of children who subsequently developed leukemia (Hjalgrim et al., 2002; Taub et al., 2002; Wiemels et al., 2002). The Children's Oncology Group has reported a trend toward higher incidence of AML, but not

• **Fig. 85.4** Extensive Leukemia Cutis in a Newborn Infant. (From Zhang IH, Zane LT, Braun B, Maize Jr J, Zoger S, Loh M. Congenital leukemia cutis with subsequent development of leukemia. *J Am Acad Dermatol.* 2006;54:S22–S27 with permission from Elsevier.)

ALL, in infants of mothers who consumed larger amounts of naturally occurring topoisomerase 2 inhibitors, such as those in foods high in flavonoids and phytates (Spector et al., 2005).

Clinical Manifestations

Clinical signs of leukemia may be evident at birth and include hepatosplenomegaly, petechiae, and ecchymoses. Myeloid leukemic cell infiltration of the skin (*leukemia cutis*) is present in 25%–30% of patients with congenital leukemia; a skin nodule may be the first clinical sign of leukemia (Fig. 85.4). Patients typically have multiple nodules that are freely movable over the subcutaneous tissue with a greenish-blue or dark pink discoloration of the overlying skin. It is important to perform flow cytometry and cytogenetic studies on the skin biopsy specimen; infants found to have an *MLL* rearrangement have a poor prognosis even in the absence of bone marrow involvement and should be treated aggressively (Zhang et al., 2006). When chloromas are present on the head or neck, imaging studies should be performed to assess the patient for the presence of intracranial or skull involvement. At birth many infants have respiratory distress from leukemic infiltration in the lungs. Severe respiratory distress may develop soon after birth from pulmonary hemorrhage secondary to thrombocytopenia. Some infants with leukemia may appear somnolent or have periodic apnea as a result of CNS leukostasis, caused by sludging of leukemic cells in blood vessels.

Laboratory Manifestations

Hemoglobin levels may be normal initially, but anemia soon develops as the normal postnatal decrease in red blood cell production is combined with the leukemic proliferation and expansion within the bone marrow. Total white blood cell counts (WBCs) may be normal or decreased, but leukocytosis is more often present. WBC counts of 150,000/mm³ to 250,000/mm³ or higher are common, and counts as high as 1,300,000/mm³ have been reported. There is usually a predominance of blast cells on the CBC differential. Auer rods, characteristic intracellular inclusions, may be present; they are pathognomonic of AML (Fig. 85.5).

Differential Diagnosis

A number of conditions can mimic congenital leukemia. Leukocytosis, hepatosplenomegaly, and thrombocytopenia can be seen

• **Fig. 85.5** Malignant Blast Cells With Auer Rods Present in Cytoplasm. This finding is pathognomonic of acute myelogenous leukemia. (Courtesy of Kristie White, UCSF Assistant Professor of Pathology, San Francisco, CA.)

in congenital infections such as syphilis, cytomegalovirus (CMV) infection, herpes simplex virus infection, toxoplasmosis, and bacterial sepsis. Congenital human immunodeficiency virus infection may rarely be confused with leukemia. Clonal B-cell expansion in such patients may cause lymphadenopathy. A marked but transient leukemoid reaction may occur during the newborn period in the setting of suspected or proven infection, particularly in very low birth weight neonates (Morag et al., 2008). Severe erythroblastosis fetalis can mimic leukemia. Affected infants usually have hepatosplenomegaly, large numbers of nucleated erythroblasts in the peripheral blood, and, occasionally, thrombocytopenia. Small infiltrates of extramedullary erythropoiesis in the skin are a rare manifestation, resembling leukemia cutis.

A transient leukemoid reaction (*transient myeloproliferative disorder*) occurs in many infants with Down syndrome. The leukemoid reaction usually resolves, but these infants sometimes require low-dose chemotherapy to reduce the risk of death because of end organ failure, and they are at higher risk of later development of acute leukemia (see later). Infants with neonatal neuroblastoma may have symptoms similar to those of congenital leukemia, with hepatomegaly and discolored skin nodules. CBCs are usually normal, without circulating blasts. Bone marrow biopsies and aspirates sometimes show clusters of neuroblastoma cells (see Fig. 85.1). Increased excretion of catecholamine metabolites and the presence of a primary tumor, most often intra-abdominal, are other clues that point to the diagnosis of neuroblastoma rather than leukemia.

Cellular Morphology and Immunophenotype

The bone marrow of a newborn with leukemia shows extreme hypercellularity and a marked predominance of immature cells, either myeloid or lymphoid. AML and ALL are differentiated on the basis of typical morphologic characteristics, such as the presence of granules or Auer rods (in AML), histochemical stains and immunophenotyping by flow cytometry, and chromosomal analysis. Terminal deoxynucleotidyl transferase, a DNA polymerase that catalyzes the polymerization of deoxynucleotides in thymocytes, is usually present in lymphoblasts but is only rarely present in myeloblasts. Myeloblasts are usually positive for myeloperoxidase, whereas lymphoblasts are not. AML is subclassified according to an international French–American–British (FAB) classification based on morphology and

TABLE 85.8 World Health Organization 2008 and Immunophenotypic Classification of Childhood Acute Leukemia

| WHO 2008 Classification | Antigen Expression ^a |
|---|-------------------------------------|
| Acute Lymphoblastic Leukemia | |
| B-cell acute lymphoblastic leukemia | HLA-DR, CD10, CD19, CD20, CD24 |
| T-cell acute lymphoblastic leukemia | CD2, CD5, CD7 |
| AML and Related Neoplasms | |
| AML with recurrent genetic abnormalities ^b AML with t(9;11)(p22;q23); <i>MLL3-MLL</i> | |
| AML, not otherwise specified | |
| AML with minimal differentiation (M0) | CD13, CD33, CD34 |
| AML without maturation (M1) | CD13, CD33, CD34 |

^aThe indicated diagnosis may express some or all of the indicated antigens.

^bOther genetic abnormalities omitted because of rarity in neonatal and infantile acute myeloid leukemia.

AML, Acute myeloid leukemia; WHO, World Health Organization.

Modified from the 2008 revision of the WHO classification of myeloid neoplasms and acute leukemia.

histochemistry (Table 85.8). The traditional FAB classification system has been integrated into the World Health Organization classification system, which incorporates additional information, such as genetic abnormalities, immunophenotype, and clinical features (Vardiman et al., 2009).

The immunophenotype, determined with a panel of fluorescently labeled monoclonal antibodies most often against cluster of differentiation (CD) antigens, is critical for differentiating AML and ALL (Craig and Foon, 2008). Myeloid leukemia cells are usually positive for CD13/CD33 antigens, which are markers of myeloid and monocytic differentiation. A notable exception is acute megakaryoblastic leukemia, which expresses the CD41/CD42 platelet glycoproteins and CD61, and is most commonly seen in patients with Down syndrome. Most neonatal and infant lymphoblastic leukemia cells exhibit an early precursor B-cell phenotype and often are CD1a, CD19, CD24, and CD15 positive and CD10 negative (Pui and Evans, 1999). In addition, coexpression of myeloid antigens is often present, suggesting that these leukemias arise from very immature lymphoid progenitors. Surface antigen expression is summarized in Table 85.8.

Genetics

A number of cytogenetic abnormalities have been found in association with congenital leukemia; many of these abnormalities

are independent prognostic indicators. The most frequent abnormalities involve disruptions of the mixed-lineage leukemia gene (*MLL*) at 11q23. Abnormalities of 11q23 are found in approximately 50% of infant AML cases and 70%–80% of infant ALL cases (Pui et al., 2003; Chowdhury and Brady, 2008; Van der Linden et al., 2009). These are nonhereditary, nonconstitutional abnormalities that occur in utero. In mice and in humans, the *MLL* protein positively regulates *HOX* genes, which are critical for hematopoietic development (Armstrong et al., 2002). Rearrangements in the *MLL* gene confer a poor prognosis, which worsens with decreasing age (Pieters et al., 2007). Gene expression analysis studies demonstrate a unique early hematopoietic progenitor genetic signature that distinguishes infant ALL with *MLL* rearrangements from ALL and AML in older children (Armstrong et al., 2002).

Treatment and Prognosis

The course of congenital leukemia is usually characterized by rapid deterioration and death from hemorrhage or infection. Although survival has been significantly prolonged in older children with leukemia, success has been limited in neonates with ALL. Infants with leukemia frequently present with hyperleukocytosis (blast cell count in excess of 100,000/mm³), which may result in sludging of blast cells in capillaries with resultant intracranial hemorrhage, respiratory distress, or tumor lysis syndrome, which is characterized by hyperkalemia, hyperphosphatemia, hypocalcemia, hyperuricemia, and acute renal failure. Disseminated intravascular coagulation is another common complication, especially with monocytic subtypes. Leukemic blast cells release procoagulants, causing a consumptive coagulopathy that places the neonate at risk of either bleeding or thrombotic sequelae and may be exacerbated by further leukemia cell lysis induced by chemotherapy.

Initial supportive care includes correction of metabolic and hemorrhagic complications. Transfusion of platelets and fresh frozen plasma is frequently required. Exchange transfusion is sometimes undertaken in infants to lower the WBC count and to correct metabolic abnormalities. Rasburicase, a recombinant urate oxidase enzyme, has been safely used in neonates with hyperuricemia (McNutt et al., 2006; Hobbs et al., 2010) but is contraindicated if glucose 6-phosphate dehydrogenase deficiency is suspected or diagnosed as precipitation of severe hemolysis and death have been reported (Zaramella et al., 2013).

Intensification of chemotherapy regimens have resulted in increased rates of remission and survival in both infants and older children. The contemporary chemotherapy regimens used in infants are similar to those used in older children and usually include daunorubicin, cytarabine, and etoposide, and outcomes for infants with AML are similar to those for older children, with overall survival rates of 65%–75% (Creutzig et al., 2012; Gamis et al., 2014).

Conversely, young infants with ALL fare worse than do older children with ALL, in whom chemotherapy results in a disease-free survival rate of more than 85%. Studies of infant ALL have reported rates of disease-free survival of 28%–47% (Pieters et al., 2007), which is a significant improvement from previous trials and has been associated with the introduction of hybrid regimens that combine elements from standard ALL and AML protocols, addressing the more primitive nature of *MLL*-rearranged ALL. Unfortunately, patients with congenital ALL continue to have higher relapse rates, with a disease-free survival rate of less than 20% (van der Linden et al., 2009).

Since CNS involvement is common in infants with AML and ALL, intrathecal chemotherapy is an important part of treatment. Radiation therapy, which can cause neurocognitive sequelae and secondary malignancies, is no longer routinely used. The use of hematopoietic stem cell transplant is controversial and remains an area of research in the treatment of congenital leukemia.

Transient Myeloproliferative Disorders and Leukemia in Patients With Down Syndrome

The incidence of acute leukemia in children with Down syndrome is 20-fold higher than in the general population. In Down syndrome children younger than 3 years, a rare megakaryoblastic subtype of acute leukemia predominates and is classified by the World Health Organization as myeloid leukemia associated with Down syndrome (ML-DS). ML-DS is characterized by *GATA1* transcription factor mutations and is distinct from conventional acute megakaryoblastic leukemia, which occurs in older non-Down syndrome patients, on the basis of molecular features and prognosis (Vardiman et al., 2009). The prognosis of myeloid leukemia associated with Down syndrome is favorable (Sorrell et al., 2012) and is associated with blast hypersensitivity to traditional chemotherapy agents such as cytarabine and daunorubicin (Taub et al., 1999).

Transient Myeloproliferative Disorder

Transient myeloproliferative disorder (TMD), which occurs in 4%–10% of neonates with Down syndrome, is clinically indistinguishable from AML (Malinge et al., 2009). While most cases of TMD occur in Down syndrome patients, TMD is also rarely seen in patients with no constitutional chromosomal abnormalities or with trisomy 21 mosaicism. TMD is a clonal disorder typically manifested by hepatomegaly, splenomegaly, and circulating myeloblasts. There may or may not be associated anemia or thrombocytopenia. In general, the blast count of the peripheral blood exceeds that of the bone marrow. Blast cells often have cell surface antigens characteristic of megakaryoblasts. Somatic mutations in *GATA1* have been detected in nearly all cases of TMD and myeloid leukemia associated with Down syndrome (Wechsler et al., 2002; Mundschau et al., 2003).

Most neonates with Down syndrome and TMD experience complete clinical and hematologic recovery without systemic therapy, usually within 3 months. The blast count slowly decreases in a period of 2 to 3 weeks, and the hemoglobin and platelet counts normalize. In some cases, however, spontaneous resolution does not occur, and the neonate may experience clinical deterioration manifested by progressive hepatosplenomegaly, hepatic dysfunction, coagulation disorder, ascites, and pleural or pericardial effusions. Approximately 20% of Down syndrome patients with TMD die, usually of hepatic or cardiopulmonary failure (Muramatsu et al., 2008). Treatment with low-dose cytarabine has been shown to reduce the risk of early death in the setting of high-risk TMD. The indications for starting treatment differ but generally include a WBC count of more than 50,000/mm³ to 100,000/mm³, platelet count of less than 100,000/mm³, renal or hepatic dysfunction, or cardiopulmonary compromise (Klusmann et al., 2008; Gamis et al., 2011). In some instances, complications from TMD occur in utero, and various degrees of hydrops fetalis can result.

Infants with Down syndrome and a history of TMD should undergo careful follow-up since TMD is considered to be a pre-leukemic syndrome: approximately 20% of neonates with TMD develop ML-DS within 4 years (Malinge et al., 2009). The administration of low-dose cytarabine does not appear to alter the risk of ML-DS.

Germ Cell Tumors

Germ cell tumors are neoplasms derived from primordial germ cells. They are a heterogeneous group of tumors, differing in site, age at presentation, histopathologic features, and malignant potential. They can occur in both gonadal and extragonadal sites (Horton et al., 2007). Normal pluripotent primordial germ cells migrate from the yolk sac to the embryo, and persistence and abnormal migration of these cells or lack of normal erasure of parental methylating imprinting is thought to lead to these tumors (Frazier et al., 2012).

Germ cell tumors make up 35%–40% of all neoplasms in the neonate, but only 5% of those contain a malignant component (Frazier et al., 2012). Benign germ cell tumors in the fetus and newborn are classified as either mature or immature teratomas (Isaacs, 2004). However, one or more of the germ layer derivatives may develop malignant characteristics. Germ cell tumors may arise in a variety of locations in the body, usually along the axial midline. Common sites in children include the pineal gland, neck, mediastinum, retroperitoneum, and sacrococcygeal region. In the neonatal period, most teratomas occur in the sacrococcygeal region (40% of all germ cell tumors), followed next by tumors in the neck. After puberty, teratomas most frequently occur in the gonads, particularly the ovary (Frazier et al., 2012). Yolk sac tumor (endodermal sinus tumor) is the most common malignant germ cell tumor in neonates and young children. In the neonate it most often occurs with a teratoma, often in the sacrococcygeal region (see later).

Pathology

By definition, teratomas contain tissue arising from all three layers of the embryonic disk. Ectodermal components, including glial tissue, are a major component of teratomas occurring at birth, in particular, sacrococcygeal tumors. There are often skin, hair, and tooth elements. Mesodermal components, including fat, bone, and muscle, also are present. Endodermal components include digestive tract tissue; this component generally forms a smaller portion of the tumor. The levels of hormonal markers, including serum AFP and β -hCG, are often elevated in the presence of malignant tissue within the teratoma and are useful to follow as therapy progresses. Elevated serum AFP level indicates the presence of immature endodermal sinus tissue or yolk sac elements, while elevated β -hCG level indicates the presence of embryonal carcinoma. Choriocarcinoma, which is rarely seen in newborns, manifests itself with an extremely elevated β -hCG level. Immature teratomas are defined and graded on a scale of 1 to 3 depending on the amount of embryonal tissue present (Frazier et al., 2012).

Evaluation

MRI or CT of the primary tumor is indicated to evaluate the extent of disease. Sacrococcygeal tumors should be imaged by MRI because of the possible involvement of the spinal cord. The entire abdomen is included in the imaging study to assess the extent of any local invasion, particularly involvement of the rectal wall. Chest imaging is performed to rule out metastasis. Baseline levels of serum AFP and β -hCG, which are normally elevated in newborns, are measured. Because of the variation in the levels at birth and the variation in the rates at which the levels decline to normal, these tumor markers can be difficult to interpret as measures of residual disease or recurrence. The half-life of AFP is 5 to 7 days; that of β -hCG is 24 to 36 hours.

Sacrococcygeal Teratomas

Sacrococcygeal teratomas are the most common solid tumors in newborns. The estimated incidence is 1 in 27,000 live births (Swamy et al., 2008). A minority are malignant: 10%–17% of sacrococcygeal teratomas contain yolk sac tumor (Isaacs, 2007). Malignancy is less common, only 7%–10%, in infants younger than 2 months (Frazier et al., 2012). Females are affected two to four times more frequently than males, but the malignancy rate is similar. Half of sacrococcygeal teratomas are diagnosed prenatally by ultrasonography. Polyhydramnios, nonimmune fetal hydrops, and dystocia have all been described in association with sacrococcygeal teratomas. Lack of prenatal diagnosis has been reported to carry a 20% risk of death in the first hour after birth secondary to hemorrhage (Swamy et al., 2008). Congenital anomalies, including genitourinary, hindgut, and lower vertebral malformations, are present in 15% of patients (Isaacs, 2007). In most cases the tumor manifests itself as a mass protruding between the coccyx and rectum; the mass may be quite large (Fig. 85.6). About 10% of these tumors are found only by rectal examination. Nearly all arise at the tip or inner surface of the coccyx.

Differential Diagnosis

Sacrococcygeal teratomas may be confused with meningocele, rectal abscess, pelvic neuroblastoma, pilonidal cyst, and a variety of very rare neoplasms that may occur in the sacral region. Most benign teratomas in this area produce no functional difficulties, even when marked intrapelvic extension is present. Bowel or bladder dysfunction, painful defecation, and vascular or lymphatic obstruction suggest that the lesion is malignant.

Treatment

Treatment of sacrococcygeal tumors is primarily surgical (Horton et al., 2007). The tumor should be radically excised as soon as possible because small, undifferentiated foci may proliferate and become aggressive. Removal of the entire coccyx is required. Failure to remove the coccyx carries a 30%–40% risk of local recurrence, which is sometimes accompanied by malignant elements. The survival rate for neonates with sacrococcygeal teratoma is 85% (Isaacs, 2007).

Sacrococcygeal teratomas diagnosed prenatally by ultrasonography (approximately 50% of cases) are associated with a worse outcome; the survival rate is only 30%–50% (Isaacs, 2004; Adzick, 2010). Fetal hydrops and prematurity are the main factors

• Fig. 85.6 Large Sacrococcygeal Teratoma in a Newborn Girl.

contributing to the low survival rate. If hydrops occurs before fetal pulmonary maturity, open fetal surgical intervention to debulk and devascularize the tumor is an option (Adzick, 2010).

Infants with sacrococcygeal teratoma containing malignant yolk sac elements are treated with surgery followed by chemotherapy with cisplatin, etoposide, and bleomycin. Immediate and late complications of this regimen can be significant and include hearing loss, pulmonary fibrosis, and secondary malignancy.

Renal Neoplasms

Approximately two-thirds of intra-abdominal masses in the neonatal period arise from the kidney. The vast majority of these neoplasms are nonmalignant and include polycystic or dysplastic kidney disease, hydronephrosis, renal vein thrombosis, and ectopic kidneys. The most common intrarenal neoplasm manifesting itself at birth is congenital mesoblastic nephroma (CMN), followed by Wilms tumor and nephroblastomatosis. Less common intrarenal neoplasms seen in the newborn period include rhabdoid tumor, clear cell sarcoma of the kidney, renal cell carcinoma, rhabdomyosarcoma, and lymphoma (Lowe et al., 2000). The typical clinical presentation is an asymptomatic abdominal mass detected on physical examination or by ultrasonography.

Congenital Mesoblastic Nephroma

CMN is the most common intrarenal neoplasm in the neonate. It usually behaves as a benign neoplasm, but the histopathologic subset, cellular CMN, occasionally recurs or metastasizes. The typical clinical presentation is an asymptomatic abdominal mass detected on physical examination or by ultrasonography, but hypertension due to a mass effect on the renal vasculature and hypercalcemia due to elevated renin levels are also common findings. The tumor infiltrates into normal renal parenchyma and is not encapsulated (Fig. 85.7). Specific sonographic features can help to differentiate CMN from Wilms tumor. The tumor may be diagnosed prenatally by ultrasonography, which reveals a greatly enlarged kidney distorted by the tumor. There is an increased incidence of polyhydramnios (71%) and premature labor (Glick et al., 2004).

Two histologic subtypes of CMN have been identified: the classic subtype and the cellular variant. The cellular variant usually manifests itself at an older age (>3 months) than the classic type (mean age at presentation of 1 month). Cytogenetic analysis of

• **Fig. 85.7** Congenital Mesoblastic Nephroma Compressing and Nearly Totally Replacing the Kidney.

the cellular variant shows a translocation $t(12;15)(p13;q25)$ that results in an ETV6–NTRK3 fusion protein that is identical to that found in infantile fibrosarcoma (Glick et al., 2004; Bayindir et al., 2009).

Complete surgical resection is usually an effective treatment for the classic form of CMN. Patients with the cellular variant are also treated with complete resection, but local and distant recurrences to the lungs and brain can occur. Positive surgical margins or tumor rupture during resection are risk factors for recurrence, which usually occurs within the first year following surgery. Resection and chemotherapy can successfully treat recurrent disease (Glick et al., 2004). The overall survival rate for CMN is 95%–98% (Isaacs, 2008).

Wilms Tumor

Wilms tumor, or nephroblastoma, is the most common intra-abdominal tumor of childhood, affecting 1 in 8000 children, but it is relatively rare in the neonatal period. In subsets of children with aniridia and hypospadias, the incidence is much higher. Wilms tumor is thought to arise from abnormal proliferation of metanephric cells, referred to as *nephrogenic rests*, without normal tubular and glomerular differentiation. Nephrogenic rests normally occur in 1% of newborn kidneys but often regress early in childhood.

Clinical Manifestations

Wilms tumor arises from one or both kidneys, and most children present with an abdominal or flank mass. It seldom extends beyond the midline, even though it may grow downward beyond the iliac crest. In 5%–10% of all cases, tumors involve both kidneys. Gross hematuria is a rare presenting symptom, but microscopic hematuria is found in approximately 25% of cases. Wilms tumor is seldom diagnosed at birth or during the neonatal period. Characteristics associated with an earlier presentation include bilaterality, associated aniridia or hypospadias, and a family history (Pastore et al., 1988).

Hereditary Associations and Congenital Anomalies

While most cases of Wilms tumor are sporadic, a number of conditions are associated with an increased risk of developing the tumor. These include *WT1*-associated phenotypes caused by deletions and mutations of the *WT1* gene (11p13), overgrowth syndromes, and constitutional chromosomal disorders (Scott et al., 2006).

WAGR syndrome (Wilms tumor, aniridia, genitourinary abnormalities, mental retardation) predisposes to Wilms tumor because of a deletion in *WT1* and aniridia because of a deletion of *PAX6*, which are both encompassed within a deleted region at 11p13 (Breslow et al., 2003). From a clinical perspective, if an infant has aniridia, chromosome analysis should be undertaken. If a deletion of chromosome 11p13 is found, the child should be monitored for the development of Wilms tumor with serial renal ultrasound examinations. Wilms tumor develops in approximately half of these patients. Denys–Drash syndrome, caused by missense mutations within the *WT1* gene, classically describes the triad of Wilms tumor, genitourinary anomalies, and nephropathy. The genitourinary anomalies may be severe enough to result in pseudohermaphroditism.

Hemihypertrophy, which can be either isolated or associated with various genetic syndromes, is associated with an increased risk of the development of Wilms tumor. BWS, an overgrowth disorder caused by dysregulation of imprinted genes at chromosome 11p15, is associated with an increased risk of Wilms tumor, particularly bilateral disease. Between 1% and 8% of individuals

• Fig. 85.8 Pulmonary Metastases From Wilms Tumor.

with BWS develop Wilms tumor (Scott et al., 2006). Other characteristic clinical findings include macroglossia, anterior abdominal defects, ear creases and pits, neonatal hypoglycemia, and hemihypertrophy.

Between 1% and 2% of Wilms tumor cases occur within families, but the underlying cause of familial Wilms tumor is heterogenous and mostly unknown (Scott et al., 2006).

Prognostic Factors

Important prognostic factors include the histologic assessment, the extent of disease, and chromosomal abnormalities. The presence of anaplasia is an important predictor of adverse outcome, and patients who have tumors with diffuse anaplasia fare worse than those with focal anaplasia. The presence of tumor-specific loss of heterozygosity for chromosome arms 1p and 16q is associated with a worse prognosis (Grundy et al., 2005). Patients younger than 2 years have fewer relapses, especially of distant sites, than older children.

Evaluation and Staging

Clinical staging, which includes a CT scan of the abdomen and chest, is an important factor in predicting survival; tumors with more extensive spread carry a poorer prognosis. The most common sites of metastasis are the liver and the lungs (Fig. 85.8). Tumor thrombus is occasionally noted in the inferior vena cava.

Treatment

Patients with low-stage Wilms tumor have a cure rate of more than 90%. Patients with small tumors limited to the kidney can be cured with surgery alone. Patients with intermediate-risk Wilms tumor are treated with a short course (12 weeks) of chemotherapy with vincristine and dactinomycin. More extensive disease or high-risk features, such as anaplasia, require the addition of doxorubicin and possibly other chemotherapy agents. Radiation therapy is indicated in children with diffuse abdominal disease; tumor spillage, including percutaneous biopsies, which is not a recommended diagnostic approach for pediatric renal tumors; or nonresponsive pulmonary metastases. Even patients with metastatic disease have a good prognosis, with a 70% long-term overall survival rate. Recurrent disease, which can be local or may involve metastases to the liver, lungs, or brain, is treated with additional chemotherapy and radiation therapy.

Rhabdoid Tumor of the Kidney

Rhabdoid tumor of the kidney (RTK) is an uncommon tumor of children that is one of the most lethal neoplasms of early neonatal life, with a mortality rate exceeding 80%. RTK is the second most common malignant neoplasm of the kidney in neonates, after Wilms tumor. It has a predilection for males and for infants, with median age at diagnosis of 11 months. It is often widely metastatic at diagnosis; metastatic sites include lung, abdomen, lymph nodes, liver, bone, skin, and brain. Homozygous inactivating deletions or mutations of the *INI1* gene, located in chromosome band 22q11.2, are responsible for most rhabdoid tumors (Jackson et al., 2007) and can be detected immunohistochemically. The prognosis for infants with RTK is extremely poor. The survival rate at 2 years for infants with a diagnosis before 6 months of age is less than 15% (van den Heuvel-Eibrink et al., 2011). Virtually all patients with distant metastases will have a fatal outcome. Treatment modalities have included surgical resection, chemotherapy, and radiation therapy.

Persistent Nephrogenic Rests and Nephroblastomatosis

Nephrogenic rests are residual immature metanephric tissue within a fully developed mature kidney. They normally occur in 1% of newborn kidneys but typically regress during early childhood. Although benign, nephrogenic rests have been confused with Wilms tumor in the past and are believed to have the potential for neoplastic transformation to Wilms tumor. Histologically, nephrogenic rest cells may resemble Wilms tumor and occasionally present a diagnostic dilemma, although the presence of mitoses favors Wilms tumor. Radiographically, when imaged with MRI, nephrogenic rests tend to appear less heterogeneous, demonstrate less contrast enhancement, and are smaller than Wilms tumor. Bilateral or multicentric Wilms tumors are associated with a high incidence of synchronous nephrogenic rests. When nephrogenic rests are multifocal or diffuse, they are referred to as *nephroblastomatosis*. Children with massive bilateral nephroblastomatosis often respond to therapies for Wilms tumor (Hennigar et al., 2001).

Retinoblastoma

Retinoblastoma is a malignant ocular tumor that arises from embryonic retinal cells. It occurs in the setting of hereditary and nonhereditary disease. The incidence of retinoblastoma is approximately 1 in 18,000 live births; between 250 and 350 cases are diagnosed in the United States each year (Kiss et al., 2008; Gombos, 2012). Bilateral involvement, which occurs in the setting of heritable disease, is observed in 20%–35% of patients. While the incidence of heritable retinoblastoma is constant among various population groups, the incidence of sporadic, nonhereditary, unilateral retinoblastoma is increased in poorer, tropical, and subtropical regions (Kiss et al., 2008).

Genetics

Approximately one-third of patients have hereditary disease, which is often bilateral. Patients with hereditary disease have a germline mutation in the retinoblastoma gene, *RB1*, a tumor suppressor gene located on chromosome band 13q14. The mutation is inherited from a parent or occurs during embryonic development. There is autosomal transmission with high penetrance, approximately 90%. Patients with nonhereditary disease tend to have unilateral retinoblastoma. Their disease is the result of acquired somatic mutations in both *RB1* alleles.

• **Fig. 85.9** Retinoblastoma Filling the Orbit. (Courtesy of Bertil Damat and Andrew Kao, UCSF Ophthalmology, San Francisco, CA.)

Approximately 5% of retinoblastoma patients are born with a constitutional deletion of chromosome 13, 13q-. These patients have associated constitutional anomalies, including microencephaly, macrognathia, malformed ears and thumbs, hypertelorism, microphthalmia, ptosis, short stature, cleft palate, and developmental delay.

In children with the bilateral and hereditary form, diagnosis is often at 1 year of age as opposed to on average at 2 years of age in children with the nonhereditary form (Gombos, 2012). This is due in part to early screening initiated because of the family history. In rare instances, a family history of retinoblastoma may be lacking; hereditary bilateral retinoblastoma may result from germline mosaicism in the parent.

Clinical Manifestations

Patients with retinoblastoma commonly present with leukocoria ("cat's eye"), squinting, or strabismus caused by loss of vision in the affected eye. Multifocal retinal involvement is common, occurring in 84% of cases. Intraocular spread may fill the vitreous body by extension or seeding, whereas exophytic tumors arise from the outer retinal layer and cause retinal detachment (Fig. 85.9). Extraocular spread is seen in less than 15% of patients, usually occurring by direct invasion of the optic nerve and eventually leading to subarachnoid involvement and intracranial spread. In such cases the cerebrospinal fluid may contain tumor cells. Rarely, tumors may spread by invasion of the orbit or by hematogenous dissemination to bone and bone marrow. Children with bilateral retinoblastoma are at risk of tumor dissemination to the pineal gland, a condition known as *trilateral retinoblastoma*. All patients with retinoblastoma should be evaluated initially by brain MRI for this condition. Patients with bilateral retinoblastoma are typically evaluated by brain MRI annually until age 5 or 6 years. Retinoblastoma can be variably be detected in utero by ultrasonography or MRI in patients known to carry the mutated *RBI* gene (Gombos, 2012).

The diagnosis of retinoblastoma is made by fundoscopic examination and orbital ultrasonography performed with the patient under general anesthesia. MRI of the orbit is useful to determine tumor extent and optic nerve involvement. A lumbar puncture for cerebrospinal fluid cytology is performed if there is optic nerve

invasion, but more extensive evaluation with bone marrow biopsy or bone scan is not usually necessary. Tumors are staged according to the International Classification of Retinoblastoma, on the basis of tumor size and location and the extent of vitreous and subretinal seeding (Kiss et al., 2008).

Treatment

Because extraocular spread and death from dissemination are rare, the main goal of treatment is local control and preservation of vision. Surgical enucleation is used only when there is no chance for useful vision, if glaucoma is present, or if conservative measures fail to control the tumor. Small tumors confined to the retina can often be controlled with focal consolidative therapies such as cryotherapy and laser photocoagulation. Systemic chemotherapy with agents such as carboplatin, vincristine, and etoposide is frequently used concurrently with cryotherapy and laser therapy. Intra-arterial chemotherapy with agents such as melphalan can provide directed therapy, as can brachytherapy. External beam radiation therapy is effective, but because of the late effects of radiation on bone growth and the potential for second tumor induction, aggressive local therapy and systemic and/or intra-arterial chemotherapy are preferable. Decisions about management involve multidisciplinary discussion because of the various treatment modalities.

Prognosis

The prognosis for children with unilateral retinoblastoma is excellent, with cure rates of 85%–90%. However, patients with bilateral disease have a much lower long-term survival rate because of the high incidence of second malignancies, which may occur at any point in the life span. Patients with hereditary disease can develop secondary sarcomas in the area treated with radiation therapy; they are also at increased risk of developing sarcomas in other, nonirradiated areas. Local extension of retinoblastoma confers a poor prognosis, with survival rates of less than 10% with orbital extension or distant dissemination.

Central Nervous System Tumors

Incidence and Epidemiology

Congenital brain tumors are rare (<5% of childhood CNS tumors), with an incidence of approximately one to three per million live births (Lasky et al., 2008; Hwang et al., 2012). They are defined as brain tumors identified up to 2 months of life. The incidence is likely underreported as 30% of neonates with brain tumors are delivered stillborn. Most brain tumors in infants are supratentorial, in contrast to pediatric CNS tumors. Half are gliomas, including astrocytomas. Primitive neuroectodermal tumors and medulloblastomas also occur. Atypical teratoid or rhabdoid tumor of the CNS is associated with a high mortality rate. In general, brain tumors presenting in the perinatal period carry a very poor prognosis. Mortality from congenital CNS tumors has been reported to be from 72%–93% (Hwang et al., 2012). Discussion with the family regarding prognosis and alternatives to therapy should be undertaken prenatally if CNS tumors are identified.

Clinical Manifestations

Macrocephaly is often the first sign of a congenital CNS tumor if the tumor has not been identified in utero. Signs and symptoms of increased intracranial pressure (ICP) may be present. In infants these include a bulging fontanelle, split sutures, or rapidly increasing head size. Poor feeding, vomiting, lethargy, and irritability can

also be symptoms of increased ICP. Fundoscopic examination may or may not show papilledema. Loss of developmental milestones may be detected in older infants and children. Specific neurologic abnormalities include Parinaud syndrome (impaired upward gaze secondary to increased pressure in the dorsal midbrain), cranial nerve palsies, and nystagmus. Head tilting can occur in patients with posterior cerebellar masses secondary to cervical root irritation.

Treatment

Treatment depends on the pathologic characteristics of the tumor, which usually cannot be ascertained until after birth and further imaging. An important component to therapy in neonates is usually surgical resection of the tumor. The degree of surgical resection is the single most important predictor of survival (Lasky et al., 2008). Complete resection is often not possible because tumors in infants tend to be large, highly malignant, and invasive. They are also highly vascular, making it difficult to remove the tissue without significant morbidity. Many patients also require ventriculoperitoneal shunt placement for relief of hydrocephalus.

Radiation therapy, a backbone of treatment for older children with malignant brain tumors, is avoided if possible in young infants because infants experience devastating late effects, including neurocognitive deficits and growth impairment. Adjuvant chemotherapy can play a role in treatment; this may allow necessary radiation therapy to be delayed until the child is older. Most tumor types are treated similarly to childhood CNS tumors, although the efficacy of these treatments is not clear especially in light of the limitations of radiation therapy.

Sarcomas

Soft tissue sarcomas are rarely seen in newborns. The most commonly diagnosed soft tissue sarcoma in the neonatal age group is infantile or congenital fibrosarcoma, which is classified as a low-grade nonrhabdomyosarcoma soft tissue sarcoma. The incidence in infants between age 1 month and age 12 months is five cases per million infants (Ries et al., 1999). In general, infantile fibrosarcoma is treated by complete surgical excision, although neoadjuvant chemotherapy with a variety of agents has been successfully used for tumor shrinkage, with subsequent reduction in the morbidity related to radical surgical procedures (Russell et al., 2009). The cure rates for infantile fibrosarcoma, with surgery alone or with chemotherapy and surgery, approach 100% (Kurkchubasche et al., 2000; Loh et al., 2002).

The initial evaluation of a patient with a congenital fibrosarcoma includes imaging of the primary tumor by MRI or CT and a chest CT scan. Diagnosis is made by biopsy of the lesion. The chemotherapy regimens used successfully for treatment of this tumor include vincristine, dactinomycin, and cyclophosphamide, as well as etoposide and ifosfamide. Doxorubicin, while efficacious, is generally avoided because of the risk of cardiac toxicity. The duration of therapy depends on the size, location, and response of the tumor, but the general goal is to reduce the tumor size to maximize the chances of surgical local control. Radiation therapy is usually avoided to spare the infant the associated late effects of poor growth and secondary cancers.

Rhabdomyosarcoma (RMS), the most common soft tissue sarcoma in children, is rarely seen in neonates: less than 1% of RMS cases are diagnosed in the first month of life. Congenital RMS often involves the genitourinary tract and is frequently of the embryonal subtype. Congenital embryonal RMS appears to

be associated with a specific translocation, $t(2;8)(q35;q13)$ (Meloni-Ehrig et al., 2009).

Histiocytosis

The histiocytoses are a diverse group of disorders characterized by the accumulation and proliferation of cells derived from the monophagocytic system—macrophages and dendritic cells (Isaacs, 2006). These disorders have been categorized into three classes (Table 85.9). Taken as a whole, histiocytoses can occur throughout life but peak incidence is in 1- to 3-year-old patients. Class I disorders, which are dendritic cell related, include Langerhans cell histiocytosis (LCH) (formerly known as *histiocytosis X*, *Letterer–Siwe disease*, *Hand–Schüller–Christian disease*, and *eosinophilic granuloma*) and pure cutaneous histiocytosis. Class II disorders, which involve macrophage-derived cells, include familial hemophagocytic lymphohistiocytosis (FHL) and infection-associated hemophagocytic syndrome (IAHS). Class III disorders are malignant disorders of mononuclear phagocytes and include acute monocytic leukemia, malignant histiocytosis, and histiocytic lymphoma. In addition to these three classes, other rare, noncategorized histiocytoses can occur in newborns, in particular, juvenile xanthogranuloma (JXG). The pathophysiology of the histiocytic disorders appears to be related to abnormal regulation of histiocyte activation resulting in cell proliferation and cytokine production (Isaacs, 2006).

The most common histiocytic disease seen in the fetus and neonate is LCH. About half of newborns with LCH have disease confined to the skin, while the other half have disseminated disease with resultant organ dysfunction, usually involving bone marrow, liver, or lung. Presenting symptoms of LCH in neonates can include skin lesions, hepatosplenomegaly, lymphadenopathy, and respiratory distress. Histologically, both cutaneous and disseminated LCH are characterized by granuloma-like lesions. Diagnosis is made by biopsy; Langerhans cells are positive by immunohistochemistry for CD1a and S-100.

The course of LCH is unpredictable. The pure cutaneous form of LCH usually resolves spontaneously in 2 to 3 months, whereas disseminated LCH carries a poorer prognosis, with 57% mortality (Minkov et al., 2005); prognosis depends on level of organ involvement, age of diagnosis, and progression of disease. To complicate matters, newborns with skin lesions may not develop the symptoms of disseminated disease for several weeks to months. Disseminated LCH is usually treated with chemotherapy, including vinblastine and prednisone. Recently, genetic findings in LCH include *BRAF* V600E mutations, which have been treated effectively with vemurafenib (BRAF inhibitor); use in pediatrics is being studied (Haroche et al., 2013).

FHL and IAHS are also seen in the newborn period. FHL has an incidence of approximately 1 in 50,000 liveborn children (Henter et al., 2007) and is more common in neonates than IAHS. It is alternatively known as *primary hemophagocytic lymphohistiocytosis*. The overall survival rate for newborns with FHL is only 9% unless a stem cell transplant is performed; the survival rate for newborns with IAHS is 59% (Isaacs, 2006). Newborns with these disorders commonly have fever, hepatosplenomegaly, and cytopenias. Other symptoms include liver dysfunction, neurologic symptoms, hypertriglyceridemia, elevated serum ferritin levels, and hypofibrinogenemia. Diagnostic criteria are listed in Box 85.1. Hemophagocytosis is found in the bone marrow in 76% of patients. Natural killer cell and cytotoxic T-cell activity is reduced or absent. Thirty percent of patients with FHL harbor constitutional mutations in the *PRF1* gene, which encodes an essential protein for cellular

TABLE 85.9 Classification of Childhood Histiocytoses

| Feature | Class I | Class II | Class III |
|--------------------------------------|--|---|--|
| Diseases included | Langerhans cell histiocytosis ^a | IAHS; FEL; grouped together as the hemophagocytic lymphohistiocytoses | Malignant histiocytosis; acute monocytic leukemia; true histiocytic lymphoma |
| Cellular characteristics | Langerhans cells with cleaved nuclei and Birbeck granules seen by electron microscopy; cell surface antigens include S100 and CD1a; cells mixed with various proportions of eosinophils; multinucleated giant cells sometimes seen | Morphologically normal, reactive macrophages with prominent erythrophagocytosis; process involves entire reticuloendothelial system | Neoplastic cellular proliferation of cells exhibiting characteristics of macrophages or dendritic cells or their precursors; localized or systemic |
| Proposed pathophysiologic mechanisms | Immunologic stimulation of a normal antigen-presenting cell—the Langerhans cell—in an uncontrolled manner | Histiocytic reaction secondary to an unknown antigenic stimulation (FEL) or to an infectious agent (IAHS), with erythrophagocytosis possibly reflecting foreign antigens absorbed on erythrocytes or activation of macrophages by excess lymphokine production due to abnormal immunoregulation | Neoplasm; clonal autonomous uncontrolled proliferative process |

^aPreviously known as histiocytosis X and its related syndromes of eosinophilic granuloma, Hand–Schüller–Christian disease, and Letterer–Siwe disease.

FEL, Familial erythrophagocytic lymphohistiocytosis; IAHS, infection-associated hemophagocytic syndrome.

From Ladisch S, Jaffe ES. The Histiocytoses. In: Pizzo PA, Poplack DG, eds. *Principles and Practice of Pediatric Oncology*, 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:772 [chapter 26].

• BOX 85.1 Diagnostic Criteria for Hemophagocytic Lymphohistiocytosis

The diagnosis can be established if:

1. The patient has a molecular diagnosis consistent with hemophagocytic lymphohistiocytoses (pathologic mutations of *PRF1*, *UNC13D*, *STXBP2*, *RAB27A*, *STX11*, *SH2D1A*, or *BIRC4*).
2. The patient has five of the following eight diagnostic criteria:
 - a. Temperature $\geq 38.5^{\circ}\text{C}$
 - b. Splenomegaly
 - c. Cytopenias (affecting at least two of three lineages in the peripheral blood): hemoglobin level $< 9.0\text{ g/dL}$ ($< 10\text{ g/dL}$ in infants younger than 4 weeks), platelet count $< 100 \times 10^9/\text{L}$, neutrophil count $< 1.0 \times 10^9/\text{L}$
 - d. Hypertriglyceridemia and/or hypofibrinogenemia: fasting triglyceride level $\geq 3.0\text{ mmol/L}$ (i.e., $\geq 265\text{ mg/dL}$), fibrinogen level $\leq 1.5\text{ g/L}$
 - e. Hemophagocytosis in bone marrow or spleen or lymph nodes; no evidence of malignancy
 - f. Low or absent natural killer cell activity (according to local laboratory reference)
 - g. Ferritin level $\geq 500\text{ ug/L}$
 - h. Elevated soluble CD25 level (i.e., alpha chain of soluble IL-2 receptor) $\geq 2400\text{ IU/mL}$

Other findings consistent with the diagnosis include cerebromeningeal symptoms, lymph node enlargement, jaundice, edema, rash, hepatic enzyme abnormalities, hypoproteinemia, hyponatremia, elevated VLDL level, and decreased HDL level.

HDL, High-density lipoproteins; IL-2, interleukin-2; VLDL, very low-density lipoprotein.

From Henter J-I, Horne A, Arico M, et al. HLH-2004: diagnostic and therapeutic guidelines for hemophagocytic lymphohistiocytosis. *Pediatr Blood Cancer*. 2007;48:124–131.

immune activation (Stepp et al., 1999). Several additional mutations can also cause FHL, including mutations in *UNC13D* on chromosome band 17q25 and mutations in *STX11* on chromosome band 6q24 (Trizzino et al., 2008). Patients with FHL are usually well at birth, then develop clinical symptoms by age 2 to 6 months. Constant fever, cytopenias, marked hepatosplenomegaly, and

progressive cerebromeningeal symptoms characterize the disease course. Initial treatment is with steroids and etoposide. Progressive disease usually leads to death within 4 months of diagnosis, but hematopoietic cell transplant can increase the 3-year survival rate to 64% (Jordan and Filipovich, 2008).

Patients with IAHS, whose symptoms are similar to those of patients with FHL, experience a high recovery rate (59%) when appropriate antibiotic or antiviral treatment is promptly administered (Isaacs, 2006). Leukocytosis is common in IAHS, possibly reflecting the underlying infectious cause.

JXG, a disorder of dendritic-related cells, is less common in neonates than LCH. Two forms are recognized: cutaneous and extracutaneous. Patients have one or multiple cutaneous nodules, which are reddish to yellow-brown papules on the head, neck, and extremities. Three quarters of neonates with cutaneous JXG have a solitary nodule. The nodules typically resolve spontaneously within approximately 2 years and are present at birth in 34.5% of cases (Willard et al., 2013). Survival is excellent for neonates with JXG limited to the skin and subcutaneous tissue, with no deaths reported in one series (Isaacs, 2006). Treatment is not generally indicated. Extracutaneous or disseminated JXG can involve the subcutaneous and soft tissues, liver, lung, spleen, eye, lymph nodes, and brain. Immunohistochemical stains may be required to differentiate this from LCH. Twenty-five percent of neonates with disseminated JXG do not have cutaneous lesions. Jaundice, hepatosplenomegaly, and thrombocytopenia can be seen. Although most cutaneous and extracutaneous lesions resolve spontaneously without treatment, disseminated JXG has an 11% death rate (Isaacs, 2006). Ocular and CNS involvement can cause significant morbidity. Systemic JXG is usually treated with chemotherapy and/or corticosteroids.

Hepatoblastoma

Hepatoblastoma, the most common malignant tumor of the liver in children, is an embryonal neoplasm composed of malignant

epithelial tissue. The incidence in infants is 11.2 cases per million; premature infants with low birthweights have a particularly high incidence (Feusner and Plaschkes, 2002). A second peak in incidence occurs at 6 months to 3 years of age. In neonates the female-to-male ratio is 1:6 (Isaacs, 2007). Treatment and management of hepatoblastoma in neonates are similar to treatment in young children. Histologic subtype is associated with outcome, with pure fetal histology having the best prognosis. Hepatoblastoma is associated with a number of genetic abnormalities and malformation syndromes, including BWS and trisomy 18 (von Schweinitz, 2003). Patients with sporadic hepatoblastoma have tested positive 10% of the time for a germline mutation in the tumor suppressor *APC*, the gene associated with familial adenomatous polyposis (Aretz et al., 2006).

Chromosome abnormalities in tumor tissue include trisomy of chromosomes 2 and 20. Chromosomal gains at chromosome 8 and 20 may be associated with an adverse prognosis. Patients with BWS demonstrate loss of heterozygosity at 11p15.5 (a tumor suppressor gene associated with increased morbidity and mortality), the Beckwith–Wiedemann locus. Patients with BWS should be screened for hepatoblastoma by abdominal ultrasonography and measurement of AFP levels every 3 months (Aretz et al., 2006).

The most common presenting symptom in neonates is abdominal distention. Even in the absence of distention an abdominal mass can sometimes be palpated. Anemia, fetal hydrops, and respiratory distress are other initial findings. Serum AFP level is elevated above neonatal norms in half of patients. Hepatoblastoma is occasionally diagnosed prenatally by screening ultrasonography. Tumor rupture can occur during birth, resulting in massive hemorrhage, often necessitating birth by cesarean delivery (Aretz et al., 2006).

Ultrasonography is useful to distinguish cystic and solid masses from diffuse hepatic enlargement. CT scan of the abdomen demonstrates the extent of tumor involvement, anatomic landmarks, and operability; MRI most accurately shows tumor margins and vessel involvement.

The goal of therapy is complete surgical resection. Infants with pure fetal histology whose tumors are completely resected have a 92% 24-month survival rate, and the overall survival rate in a case series of 52 patients was 86% (Aretz et al., 2006). A lobectomy of the involved portion of the liver is performed if one lobe is free of malignancy and there is no evidence of distant metastases. For unresectable but nonmetastatic tumors, initial treatment consists of chemotherapy with cisplatin and vincristine. If adequate tumor shrinkage results, the tumor is then resected. Orthotopic liver transplant has been used in patients with unresectable, nonmetastatic hepatoblastomas in conjunction with chemotherapy.

Hepatic Hemangioendothelioma

Hepatic hemangioendothelioma, also referred to as *hepatic hemangioma*, is a benign vascular tumor of the liver; it is the most frequent liver tumor of infants (Warmann et al., 2003). The disease is classified into three subtypes: focal, multiple, and diffuse hepatic lesions. Some patients also have cutaneous hemangiomas. While some infants with small tumors are asymptomatic, infants with larger tumors can have multiple symptoms, including abdominal distention, respiratory distress, high output cardiac failure, and consumptive coagulopathy. The diagnosis is often suspected prenatally when a hepatic mass is detected by ultrasonography. The diagnostic evaluation usually includes abdominal ultrasonography and CT or MRI. If imaging studies fail to provide a diagnosis,

then a biopsy can be considered. Infants with focal or multifocal disease without evidence of cardiac failure can usually be carefully observed with periodic physical examinations and ultrasound examinations. Various modalities have been used for symptomatic infants, including use of corticosteroids, use of corticosteroids with vincristine, embolization or artery ligation, surgical excision, and use of antiangiogenic chemotherapy agents (van der Meijs, 2009; Qureshi et al., 2015). Propranolol, which is used for treatment of cutaneous hemangiomas, may also be effective for treatment of hepatic hemangiomas (Vergine et al., 2015). The overall survival rate for fetal and neonatal focal hemangioma is 86%; the overall survival rate for fetal and neonatal multifocal disease is 71% (Isaacs, 2007).

Treatment Considerations in Infants

Chemotherapy Dosing

Neonates and infants experience more frequent and more severe side effects and late effects from chemotherapy compared with older children and adults. This is likely due to age-related differences in body composition, drug bioavailability, and drug metabolism. Infants have an increased amount of total body water, decreased activity of drug-metabolizing enzymes, particularly cytochromes P450, and less efficient renal function. To compensate for these differences, specific chemotherapy dosing protocols have been developed for neonates and infants. The doses for systemic chemotherapy are reduced overall and are frequently calculated by weight instead of by body surface area. Paradoxically, the volume of the cerebrospinal fluid in relation to body surface area is much greater in young children than in adults; accordingly, the doses of intrathecal chemotherapy are adjusted for age to avoid the underdosing of young infants with leukemia.

Radiation Effects

The use of radiation therapy in newborns is reserved for acute life-threatening situations in which the benefits of radiation therapy clearly outweigh the risks of adverse late effects, which include growth impairment, cognitive impairment, and the risk of secondary malignancies. The goal is to minimize the use of radiation as much as possible, while not compromising disease-related outcomes, to spare the infant potentially morbid treatment-related side effects.

Pain Management

Infants experience pain and should be treated with adequate pain medication. Signs of pain in the neonate can be subtle and can include crying, grimacing, poor feeding, tachycardia, and high blood pressure. Acetaminophen can be an effective analgesic in infants, but it must be used judiciously to avoid the masking of a fever that could signify an infection, particularly if a central line is in place or in the setting of neutropenia. Use of nonsteroidal antiinflammatory medications is usually avoided in patients with cancer because of the risks of bleeding due to interference with platelet function in the setting of chemotherapy-induced thrombocytopenia. Narcotics can be used as needed provided that adequate monitoring of side effects such as respiratory depression is in place. Narcotics can produce physical dependence when used for more than 1 week, and the doses may need to be tapered to avoid withdrawal symptoms.

Nutrition

Adequate nutrition is particularly important for neonates and infants. Patients might require supplemental nutrition via a nasogastric tube or intravenous parenteral nutrition. A nutritionist should be consulted to help assess the infant's nutritional needs. Breastfeeding can usually be continued in neonates with malignancy.

Intravenous Access

Most neonates and infants with diagnosed cancer will require a central venous catheter to facilitate delivery of chemotherapy, blood product support, and parenteral nutrition. Some chemotherapy agents, such as vincristine and doxorubicin, are vesicants and can cause severe skin and subcutaneous burns if inadvertently infiltrated underneath the skin, which is a more common occurrence with peripheral intravenous access. The type of central line inserted depends on the size of the infant and the specific needs associated with the chemotherapy regimen.

Transfusions

Cancer patients frequently require blood product supports to correct life-threatening cytopenias and coagulopathies, which can be secondary to the underlying malignancy or treatments directed against the malignancy. To minimize the risk of transfusion-associated infections and complications, a number of guidelines exist. These include the use of CMV-negative blood to prevent transmission of CMV, which is potentially life threatening in an immunocompromised infant; the use of irradiated blood products to prevent the possibility of life-threatening graft-versus-host disease; and the use of leukocyte-depleted blood products to minimize nonhemolytic febrile or allergic reactions. Use of donor-designated blood is usually discouraged in infants with congenital leukemia, given the possibility of the need for future related donor hematopoietic stem cell transplant.

Immunizations

Immunizations are generally avoided until the patient has not been receiving chemotherapy for at least 6 months. In addition, close contacts of the patient should receive the inactivated polio vaccine rather than the live oral polio vaccine. There is no contraindication to immunization of first-degree relatives with the varicella vaccine. However, any person in whom a rash develops after the vaccination should be kept away from the patient.

Psychosocial Considerations

Social services and psychological support are essential for families. These services are usually best coordinated through the efforts of a multidisciplinary team composed of nurses, social workers, case managers, and the pediatric oncologist.

Late Effects

Infants who receive treatment for cancer during the first year of life are at risk of many late effects directly related to chemotherapy, surgery, and radiation therapy. Infants in the neonatal period will be particularly susceptible to therapies affecting normal

growth and development. Information about late effects of treatment and suggested screening after childhood cancer may be found on the Children's Oncology Group website (<http://www.childrensoncologygroup.org>). Infants require follow-up evaluations at routine intervals by a pediatric oncologist (or multidisciplinary cancer survivor team), who can help identify appropriate screening tests and support.

Conclusion

Cancer in the neonatal period is rare but must be diagnosed and treated promptly with careful attention to the epidemiologic and clinical features that differ from those of older children with similar malignancies. There are special challenges in treating the neonate with cancer, including the newborn's unique physiologic status, which results in marked susceptibility to immediate and late adverse effects of treatment. Careful teamwork is necessary among the neonatologist, pediatric oncologist, surgeon, radiation therapist, nurse, and social worker to support and treat the patient and the family.

Acknowledgments

The authors acknowledge the contributions of Katherine K. Matthey and Mignon Loh, who served as authors of this chapter in previous editions of this book.

Renal Development

IRENE MCALEER

KEY POINTS

- Renal organogenesis is a complex interaction between gene stimulation of planned growth and complementary apoptosis that allows appropriate development of the functioning renal organ system, vascular bed, and intertwined genital system.
- The renin–angiotensin system (RAS) is critical to normal renal development through delicate interaction between the maternal–placental RAS and the developing fetal RAS that has central hormone-specific and sex-specific configurations that help the developing vascular and renal organogenesis.
- Fetal development, genetic factors, and environmental factors control ultimate nephron numbers. Lower than normal nephron numbers at birth may predispose the adult to renal and cardiac disease.

The human kidney, specifically the metanephric kidney, is an extremely complex organ that has more than 25 functionally and morphologically different distinct cell types situated to perform vitally important functions for the developing human. These actions include filtering waste products and maintaining electrolyte and fluid homeostasis, bone mineralization, blood pressure, and blood composition (O'Brien and McMahon, 2014; Little, 2015). The nephron is the portion of the kidney that performs these functions. The total complement of human nephrons averages 900,000–1,000,000, and their development is complete in the human by 34–36 weeks' gestation. Any further growth of the kidney is due to an increase in the size of the individual nephrons rather than an increase in nephron number.

Renal organogenesis is a complex and incompletely understood process. Factors affecting maternal and fetal health, including environmental factors in utero, can lead to failure of normal morphogenesis, resulting in congenital anomalies of the kidney and urinary tract. If the complement of nephrons is decreased by prematurity, low birth weight (LBW), or exposure to environmental agents causing damage to the developing renal system, adult renal disease and hypertension may occur subsequently (Little, 2015; Nuyt and Alexander, 2009; Maringhini et al., 2010; Dötsch et al., 2012). Many steps in the development of the human kidney are unknown but are extrapolated from the study of animal models. This chapter will review known (and postulated) molecular and cellular mechanisms of renal development, the impact of

environmental factors on the developing fetal kidney, and the long-term risks of renal disease and hypertension into adulthood (Andrew and Yelon, 2015).

Factors Influencing Organogenesis

Organogenesis, or organ formation, begins with early patterning of cell groups by the expression of genes and transcription factors that act to determine cell fates specific to a given organ (Andrew and Yelon, 2015).

Transcription factors, generally ribonucleic acids (RNAs) directed by DNA information, are incorporated into larger molecular networks and ultimately direct downstream signaling pathways. Transcription factors may have different purposes in each organ system that they are responsible for developing. Similarly, signaling pathways are used repeatedly in the development of different organs, and these same pathways may also be used in multiple stages of differentiation in the same organ.

Signaling pathways establishing epithelial morphogenesis by allowing cell polarity, bending, and folding to shape the developing tissues have been found to interact with the loose mesenchyme surrounding the epithelia through signaling between the two tissue types. This reciprocal induction between epithelia and mesenchyme is well illustrated in kidney development, where expression of the transcription factor Wilms tumor 1 (WT1) in the metanephric mesenchyme leads to glial cell–derived neurotrophic factor (GDNF) expression critical for the outgrowth of the developing epithelial ureteral bud. Reciprocally, the ureteral bud then signals back to the metanephric mesenchyme to induce formation of the renal nephron units. There is a delicate balance between the interplay between the ureteral bud and the developing mesenchymal metanephros to allow tissue differentiation into the final renal unit.

Enhanced imaging, ex vivo organ culture, and computational strategies have advanced our understanding of the physical forces inside and outside the cells in organ development (Andrew and Yelon, 2015). Study of different species has led to better understanding of the role of the extracellular matrix in regulating the mechanical properties of the developing tissues. The extracellular matrix also provides substrata for cell migration, rotation, and elongation necessary for organ development. Most of this research is in nonhuman tissue at present, but the basic understanding of generalized organogenesis is important in determining the steps critical in

human organ development, with potential implications for regenerative medicine as well. Unfortunately, the organisms most extensively studied are *Planaria* species, which have stem cell populations throughout their bodies able to replace almost everything that is damaged or missing, unlike in human and mammalian species.

Development of the Renal Vascular Bed

The vascular systems of all vertebrates are highly organized branched networks of arteries, veins, and capillaries. The circulatory system in combination with the hematologic system is the first functioning physiologic system to develop in embryogenesis (Crivellato, 2011). Development of the cardiovascular and hematologic systems must occur in tandem because simple diffusion of oxygen and nutrients would be insufficient for organ development as the embryo enlarges. Formation of the vascular system is therefore crucial for proper tissue growth and differentiation, delivery of oxygen and nutrients to the developing organism, and removal of waste.

Vasculogenesis and angiogenesis play a primary role in determining patterning of the developing embryo through the paracrine action of the endothelial cells. Blood vessels are critical for organ development, differentiation, and postnatal remodeling. There is a reciprocal relationship, with the developing organ providing signals to the endothelial cells of the developing vasculature, while the endothelial cells signal patterning instructions for organ formation. Vascular development (vasculogenesis) begins shortly after gastrulation when the blood islets form in the yolk sac and angioblast precursors form in the head mesenchyme and the posterior lateral plate mesoderm. The vascular precursor cells are present in the metanephric blastema. Local environmental cues initiate the differentiation of the endothelial layer in the developing kidney as evidenced by formation of the renal vascular tree after transplant of different extrarenal endothelial cells to the developing renal bed in mouse kidneys. Angiogenesis occurs mostly later in embryogenesis by increasing the previously laid vascular bed by sprouting, bridging, and intussusceptive growth. Ultimately, the primitive vessels branch, prune, and specialize to accommodate the probable function of each respective organ that they feed. Oxygen tension and hemodynamic forces are critical for developing the delicate patterns specific to the local vasculature. Angiogenic growth factors are necessary for development as well as organ patterning. The most important factors responsible for angioblast differentiation and tube formation are vascular endothelial growth factors (VEGFs). VEGFs are found early in blood vessel patterning and later help modulate endothelial maintenance in normal tissues before and after birth. The endothelial cells themselves are the source of these proteins. VEGF also helps mobilize blood elements from the bone marrow through interactions with hematopoietic stem cells there (Crivellato, 2011). The development of the area-specific branching pattern is likely due to local factors and different local progenitor cell populations. The podocyte epithelial cells in the developing glomerular region secrete large amounts of VEGF, stimulating increased branching of the vessels forming in this area (Fig. 86.1). Fibroblast growth factors (FGFs) are heparin-binding growth factors that interact with endothelial cell surface receptors. Their primary purpose is to help control branching morphogenesis of the vascular tree during organogenesis. The postglomerular vascular bed with its close alignment to the vasa recta in the renal tubule structures is likely regulated by angiogenic factors such as VEGF secreted by the tubules themselves. Postnatal development of the vasa recta has been found to be mediated by VEGF as well. Thus renal vasculature development occurs

through simultaneous vasculogenic and angiogenic means. VEGF is critical in the regulation of blood vessel formation in the kidney. VEGF is also responsible for the coordinated development of the glomerulus and renal tubular development at the same time it is regulating vasculogenesis. Current animal model studies suggest that postnatal branching may be mediated by the renin–angiotensin system (RAS).

The renal vascular bed is unique compared with other organ systems. The kidneys compose less than 0.8% of the human body weight but receive 20% of the cardiac output at any given time (Herzlinger and Hurtado, 2014). The volume of blood sent to the kidney is critical for its task of clearing the body of metabolic waste, as well as maintaining fluid and ion homeostasis in the bloodstream. The renal artery enters the kidney near the central portion of the kidney or hilum, which is close to the medulla of the kidney. Although the renal artery is proximal to the medulla of the kidney, 90% of the blood it delivers is sent directly to the glomerular capillary bed in the periphery of the kidney, and only 10% is delivered to the medulla.

The arterial structure of the kidney is critical for directing blood primarily to the glomerulus. The mechanisms for this patterning during development are not well understood, but as development proceeds, the medullary portion of the arterial tree has very little branching, whereas the cortical arteries have extensive branching, especially the afferent arterioles surrounding the glomeruli.

For appropriate renal function the glomerulus endothelium is very permeable to fluids and low molecular weight solutes. Additionally, the resistance of the renal vasculature surrounding the glomerulus is very high to allow the ultrafiltrate produced to flow through the urinary space at 125 mL/min. These high-resistance arterioles allow the amount of fluid emanating from the glomerular capillaries to be about 50 times greater than the fluid outflow of other capillary systems in the body. In contrast, the peritubular capillaries have a fairly high oncotic pressure, allowing them to reabsorb solutes and fluids that may be lost by the high glomerular filtration rate (GFR). There is a complementary interplay between the renal tubules reabsorbing fluid, electrolytes, and solutes from the glomerular filtrate and the peritubular capillaries returning these substances to the systemic circulation because of their high oncotic pressure pull.

The vasa recta is an additional renal capillary bed adjacent to the renal tubules in the medulla. These vessels act by delivering oxygen and nutrients to the medulla and also return electrolytes and solutes reabsorbed by the medullary renal tubules. The long looped arrangement of the vasa recta close to the loop of Henle is critical for urine concentration by conservation of water through increased osmolarity in this region in the renal medulla (Herzlinger and Hurtado, 2014). The blood is ultimately collected in the venous system at the cortical medullary region of the kidney and flows out of the kidney through the renal vein.

Renal Morphogenesis

The mammalian urogenital system develops from the intermediate mesoderm. The paired epithelia nephric ducts arise dorsally and elongate caudally on the right and left sides of the embryo until they induce development of the pronephric and mesonephric duct formation from intermediate mesenchymal mesoderm. These ducts elongate until they reach and fuse with the cloaca, which is the bladder and urethral precursor. The primitive tubules that develop as the pronephros and mesonephros are transient and have minimal function, and only a portion remains of the mesonephric tubules

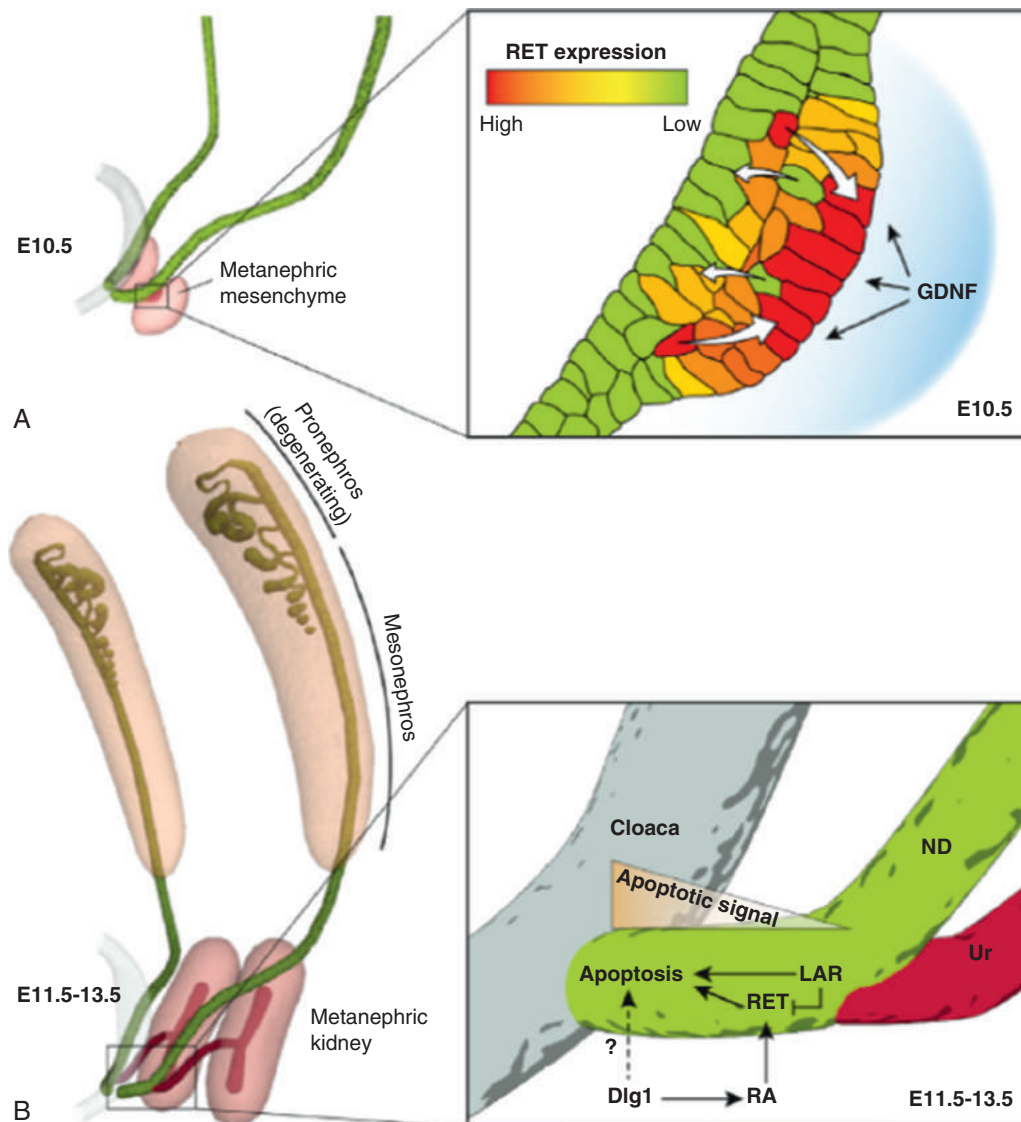

• **Fig. 86.1** Anatomy of the Renal Vascular Bed. Reconstructed scan of an entire mouse kidney corrosion cast by nano computed tomography (A–C). Thresholding for large vessels (A) illustrates the stereotypic architecture of the renal artery and its major branches. As thresholding is adjusted to visualize smaller vessels, the cortical arterial tree up to the level of the intralobular arteries is detected (B). Finer thresholding allows the visualization of the complex architecture of the cortical microvasculature (C). (D) Corrosion cast of rat kidney images by scanning electron microscopy. The glomeruli (*g*), peritubular capillaries (*pt*), and vasa recta (*vr*) are easily visualized. Patterning the renal vascular bed. *Semin Cell Dev Biol.* 2014;36:50–56.)

as a portion of the male reproductive system (O'Brien and McMahon, 2014).

The metanephric kidney arises from the posterior nephric duct through reciprocal signaling induction between the metanephric mesenchyme and nephric duct causing the ureteral bud to form. Human metanephric differentiation starts at about 5 weeks' gestation, and the first functioning nephrons are formed at about week 8. The ureteral bud will then invade the metanephric mesenchyme to initiate the mesenchymal to epithelial differentiation giving rise to the glomerulus–nephron–collecting duct system of the mature kidney. The requirement for intermediate mesoderm appears to be regulated by bone morphogenetic protein (BMP) signaling, which is also required for maintenance of the pronephric duct

gene expression to allow survival and differentiation of the developing nephric duct.

Paired box genes (*PAX2* and *PAX8*) appear to be necessary to drive nephric duct development, elongation, and maintenance as well (Stewart and Bouchard, 2014). The final stage in early nephric development is the separation of the genital tract from the urinary tract. Once the ureteral bud extends from the nephric duct, the urinary tract separates the ureter from the common nephric duct through apoptosis to form the new ureterovesical junction into the cloacal structure that will be the urinary bladder. This apoptosis is most active at the caudal region and less so at the ureteral bud branching point. The apoptosis occurs through downregulation of RET (receptor tyrosine kinase) activity. RET is still needed for

• **Fig. 86.2** Interaction between mesenchymal and nephric duct epithelial tissues drives cell sorting to form the ureteric bud and programmed cell death during ureter maturation. (A) Ureteric bud evagination involves RET tyrosine kinase-dependent cell sorting (white arrows) to assemble the highest RET-responsive cells toward glial cell-derived neurotrophic factor (GDNF) secreted from the metanephric mesenchyme. (B) A graduated apoptotic signal drives elimination of the common nephric duct. Apoptotic cell death involves Dlg1 and retinoic acid (RA) signaling from the mesenchymal compartment, which appear to act through RET within the common nephric duct. Apoptosis additionally requires the expression of LAR-family receptor protein tyrosine phosphatases in the common nephric duct, which act partially by down-regulating RET pro-survival signaling. E, Embryonic day; ND, nephric duct; Ur, ureter. (From Stewart K, Bouchard M. Coordinated cell behaviours in early urogenital system morphogenesis. *Semin Cell Dev Biol.* 2014;36:13–20.)

ureteral remodeling but at an expression level lower than that needed for generation of the ureteral bud branching off the nephric duct. Appropriate elimination of the common nephric duct is necessary for normal urinary tract function. Absence or delay in ureteral remodeling may result in ureteropelvic junction obstruction. Overactivation of apoptosis of the common nephric duct may result in vesicoureteral reflux (Stewart and Bouchard, 2014; Fig. 86.2).

Development of the ureteral bud requires an active RET–GDNF pathway. GDNF located in the metanephric mesenchyme adjacent to the nephric duct activates ureteral bud development by activation

of RET located along the nephric duct. If RET is absent, ureteric induction fails, but the ureteral bud forms ectopically in studies where GDNF is cultured next to the nephric duct (Blake and Rosenblum, 2014). Wnt pathway factors, particularly factor 11, and FGFs upregulate GDNF to help with branching of the developing ureteral nephron tree.

Once the ureteral bud has been stimulated to extend out to the developing metanephric mesenchyme, it begins to branch, forming the ureteric tree, which occurs only at the tips of ureteric tips with RET–GDNF reciprocal signaling, which upregulates RET–Wnt11, further upregulating GDNF secretion. This ureteral

signal to release RET is localized to the cap mesenchyme. With continued proliferation, elongation, patterning, and segmentation, the specific functioning regions of the nephron form the recognizable adult nephron (glomerulus, proximal tubule, loop of Henle, distal tubule), which all connect back to the collecting duct (Fig. 86.3).

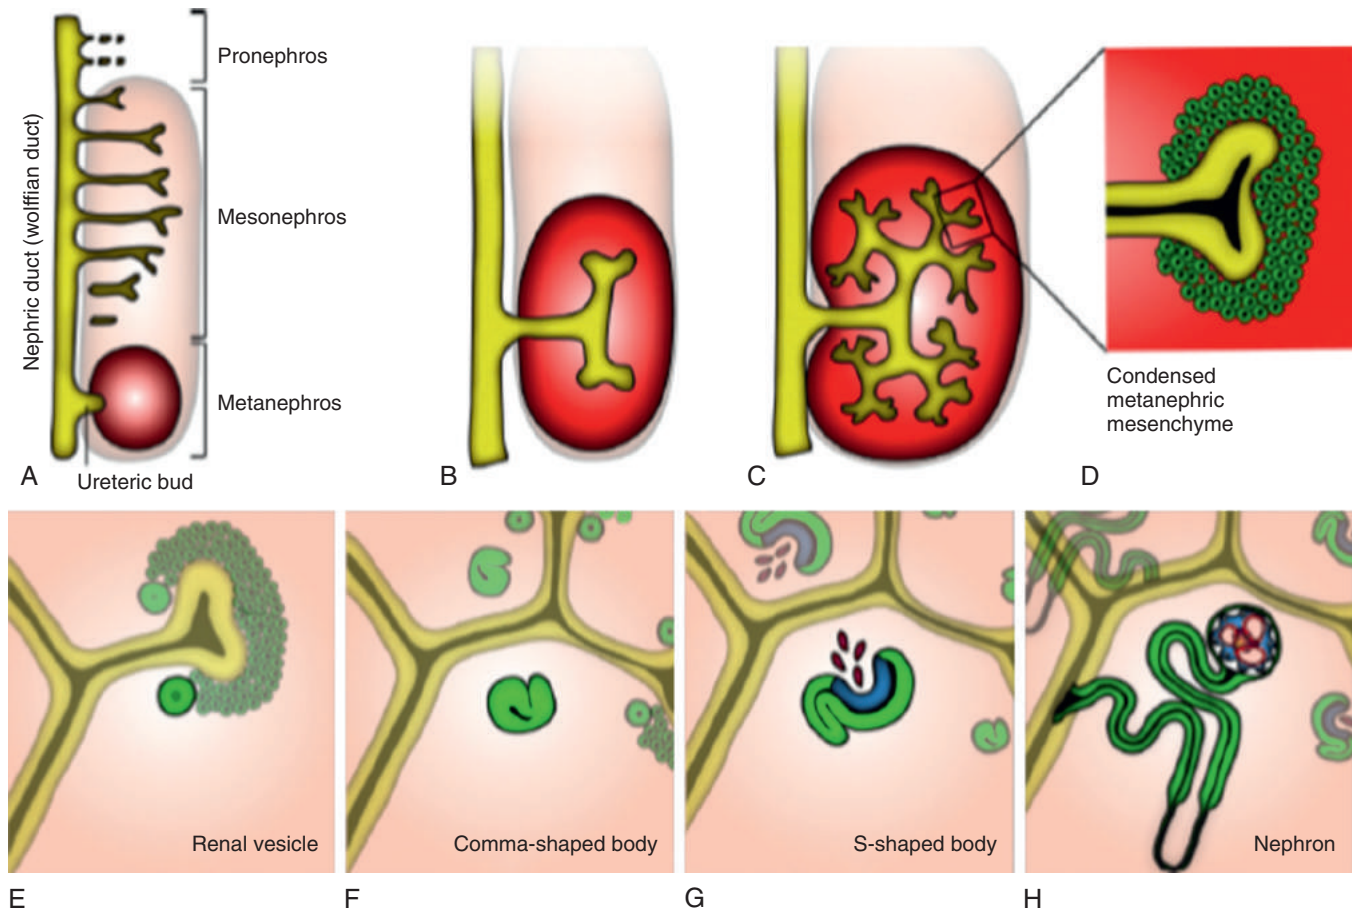

Once the ureteral bud epithelium invades the metanephric mesenchyme at the cap mesenchyme region, this mesenchyme

condenses around the ureteral bud tips under the influence of Wnt genes (Dressler, 2009). The renal vesicle, the first epithelial structure that will become the future nephron, is activated by the developing ureteral bud. The next phase is the development of the comma-shaped bodies as the first condensation of the renal vesicle metanephric mesenchyme. The formation of the cleft in the comma-shaped bodies denotes the development of the S-shaped bodies, which will ultimately initiate the development of the renal nephron (Fig. 86.4). The S-shaped bodies are derived from the cap mesenchyme and will become the glomerular tuft once the endothelial cells infiltrate this area of the developing nephron. The axis of the developing nephron is determined by the S-shaped body after it fuses to the ureteral tip. The proximal end of the S-shaped body will be the glomerulus, while the distal end will fuse to the ureteral bud branching system as the collecting duct. The S-shaped phase of development is when the nephrogenic and vasculogenic processes connect because of secretion of VEGF from the podocytes in the S-shaped body and attract migrating vascular endothelial cells to the S-shaped body cleft (Schell et al., 2014; Fig. 86.5).

With time and continued development, the ureteral tip and cap mesenchyme decrease in size. Ureteric branching ceases in the human at around week 14–15 of gestation. The human kidney is multipapillate, with about 8–15 lobes, each having about 15 generations of collecting duct branching. The extensive patterning and segmentation that occur in nephron development are driven by anchor genes that have absolute specificity for each cell compartment where they are located in the developing embryo. The kidney alone has more than 15 distinct anatomic compartments. To date, 37 anchor genes have been defined for only six subcompartments in the kidney. The actions of these genes are not yet well known, but the anchor genes may be responsible for initiating differentiation of the various compartments of the nephron by releasing promoters and tissue factors to the local mesenchyme to initiate formation of the functioning renal unit (Little, 2011).

Human nephron development is compared with mouse development to extrapolate similar or speculated steps in development that may be the same (see Fig. 86.5). The human nephron

• **Fig. 86.4 Nephron Development.** (A) In mammals the kidney develops from the metanephric mesenchyme on invasion of the ureteric bud from the nephric duct. (B, C) The ureteric bud starts branching within the growing metanephric mesenchyme. (D) The mesenchyme condenses around the ureteric bud tips, forming the Six2-positive cap mesenchyme. (E) Renal vesicles form from the condensed cap mesenchyme. (F) A cleft develops in the comma-shaped bodies. (G) Podocyte progenitors start to attract angioblasts in the S-shaped body. Glomerular development: shaping the multi-cellular filtration unit. *Semin Cell Dev Biol.* 2014;36:39–49.)

complement may differ by about 10-fold between individuals, with variability in number based on age, race, and gestation events such as birthweight, prematurity, and in utero exposure to maternal factors (smoking, malnutrition, diabetes, and other agents) (Little, 2015).

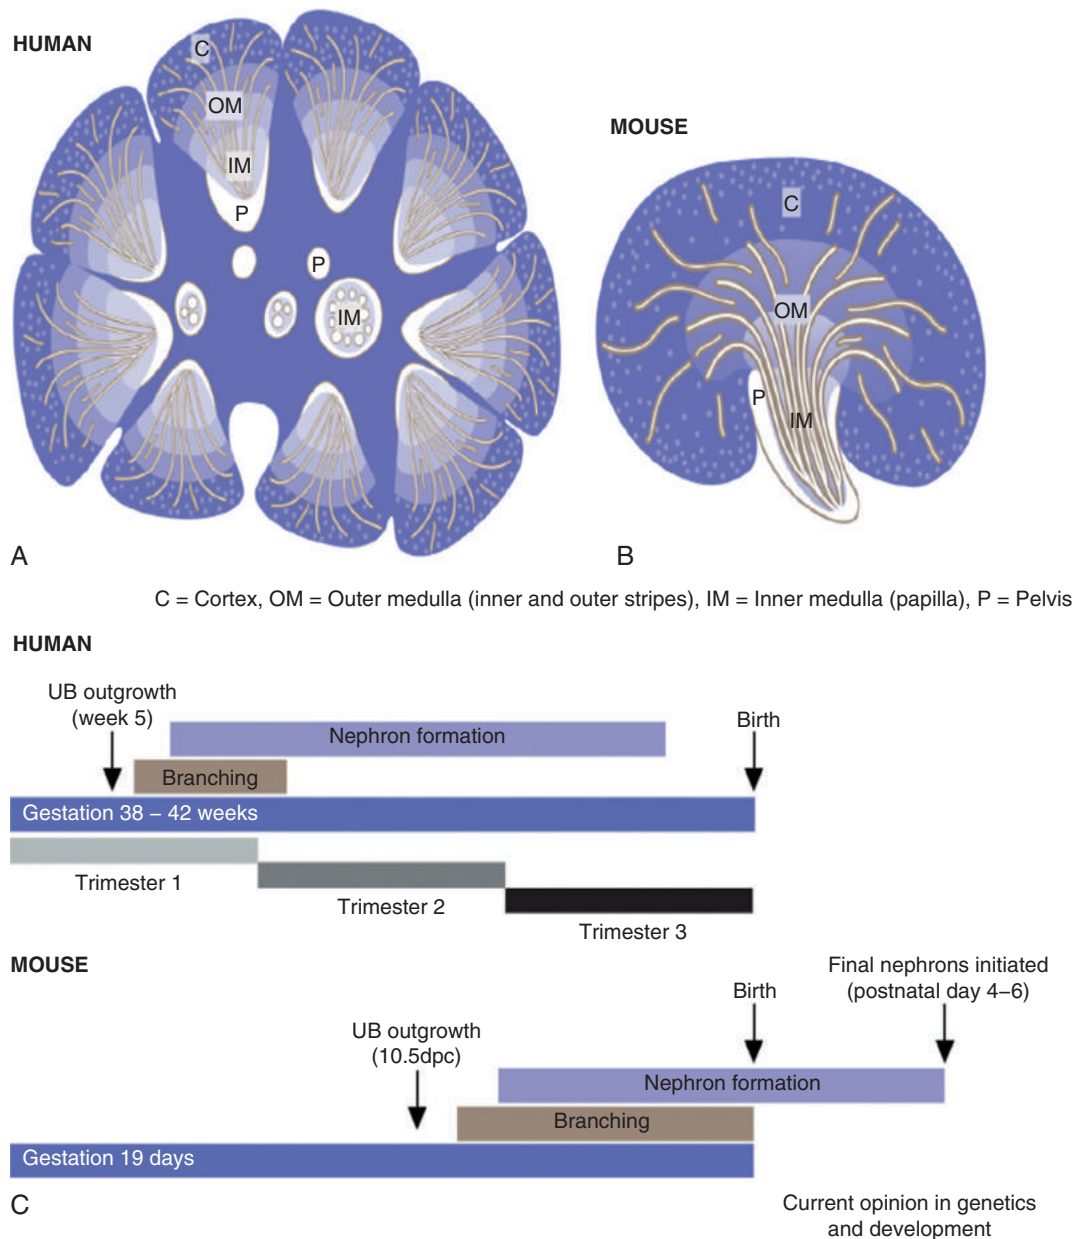

Glomerular Development

Glomerular formation occurs in stages and is dependent on specific cell type signaling within the glomerular capillary. Malformation of any component of glomerular development may result in decreased filtration ability of the nephron, typically characterized by proteinuria.

Development of the glomerulus is intricately linked with the development of the renal tubule. Glomerular formation begins at the S-shaped body stage of nephron development. Glomerular endothelial progenitors are found adjacent to the nephron developing podocytes at the cleft of the S-shaped structure during this stage. An initial capillary loop will ultimately mature into six to eight capillary loops representing the mature glomerular capillary tuft. This migration of glomerular endothelia progenitors is likely

due to VEGF secretion by the local podocytes. The amount of VEGF released by the podocytes controls capillary development by proangiogenic and antiangiogenic signaling (Herzlinger and Hurtado, 2014). It is critical that the podocyte foot processes connect tightly or the filtrate from the afferent arteriole will allow leakage of larger molecules such as protein and larger solutes, causing loss of important proteins, fluid, and solutes that need to be returned to the systemic vasculature. These foot processes are integral to the glomerular filtration barrier (Fig. 86.6).

Vasculogenesis starts during the S-shaped body stage of glomerular development as mentioned earlier when expression of several VEGFs from the glomerular podocytes occurs, inducing migration of endothelial cells to the cleft of the S-shaped body. Blockage of these factors in mice causes renal disease resembling preeclampsia and end-stage renal failure by 9 weeks of age (Schell et al., 2014). VEGF-A secretion by the podocytes of the S-shaped body causes fenestration of the podocytes near the glomerular basement membrane in proximity to the glomerular endothelial cells, possibly allowing limited transmission of fluid from the vascular tuft into the glomerulus, but the function and mechanism of these fenestrations are not well understood at present.

• **Fig. 86.5** Comparative timeline of kidney development between human and mouse. The human (A) and mouse (B) kidney illustrating the anatomic differences. The human kidney consists of 8–15 lobes, each with a branching ureteric tree and inner medulla (IM; papilla), while the mouse kidney is unipapillate. (C) Comparative developmental timeline of human and mouse nephrogenesis identifying the duration of gestation, timing of initial ureteral bud (UB) outgrowth, period of ureteric branching, and period of nephron formation. Note the prolonged period of nephron formation in the human after the end of branching in comparison with the mouse. Note also that the final nephron formation in the mouse occurs in the immediate postnatal period. C, Cortex; dpc, date post conception; OM, outer medulla, P, pelvis. (From Little MH. Improving our resolution of kidney morphogenesis across time and space. *Curr Opin Genet Dev.* 2015;32:135–143.)

WT1 is a zinc finger transcription factor, with four different isoforms isolated at present. It is thought to be a transcription factor that binds to DNA as well as messenger RNA as either a repressor or an activator in different organs during development. Studies in mice showed that WT1 is important for genitourinary development. In humans, WAGR syndrome (Wilms tumor, aniridia, genitourinary abnormalities, and mental retardation) is caused by interstitial deletion of the 11p13 locus, where the *WT1* and *PAX6* genes are located. Similarly, *WT1* mutations are

thought to contribute to the abnormalities seen in Denys–Drash syndrome (mesangial sclerosis, Wilms tumor, and gonadal dysgenesis). Studies of *WT1* absence or mutations have been done extensively in mice, showing that *WT1* is essential for podocyte development and possibly for podocyte maintenance. Further study in humans is needed to better understand *WT1* interactions in normal genitourinary development as well as what aberration of *WT1* expression does in disease states (Schell et al., 2014).

• **Fig. 86.6** Specification of podocyte cell-cell contacts. (A) In the renal vesicle and comma-shaped body stage, the podocyte progenitors display a typical epithelial morphology with apical cell-cell contacts. (B) During the S-shaped body stage, apical membranes expand and cell contacts appear to shift to the basal sides of podocytes. (C) At the capillary loop stage of immature glomeruli, the podocyte cell-cell contacts are located at the basal side. (D) At mature glomeruli, the podocyte foot processes form a specialized cell-cell contact, the slit diaphragm. (From Schell C, Wanner N, Huber TB. Glomerular development: shaping the multi-cellular filtration unit. *Semin Cell Dev Biol.* 2014;36:39–49.)

Ureteral Growth and Development

The ureters are muscular tubes conveying urine from each renal pelvis to the urinary bladder. The upper ureter, leaving the kidney at the renal pelvis, is a thin-walled, funnel-shaped tube that thickens as it passes through the abdomen and enters the bladder obliquely to terminate at the bladder trigone. There are two tissue components to the ureter: the specialized endothelial-lined lumen and the outer mesenchymal coat consisting of the lamina propria, multilayered smooth muscle, and the outer tunica adventitia. This outer tunica adventitia also contains ascending and descending blood vessels, nerves, and lymphatics. The ureter does not passively allow the urine to drain from the kidney to the bladder but directs the urine to the bladder with unidirectional peristaltic contractions propelling

the urine to the bladder. The peristaltic waves, triggered by pacemaker cells, cause depolarizing contractions in the smooth muscle cells located in the ureteropelvic junction.

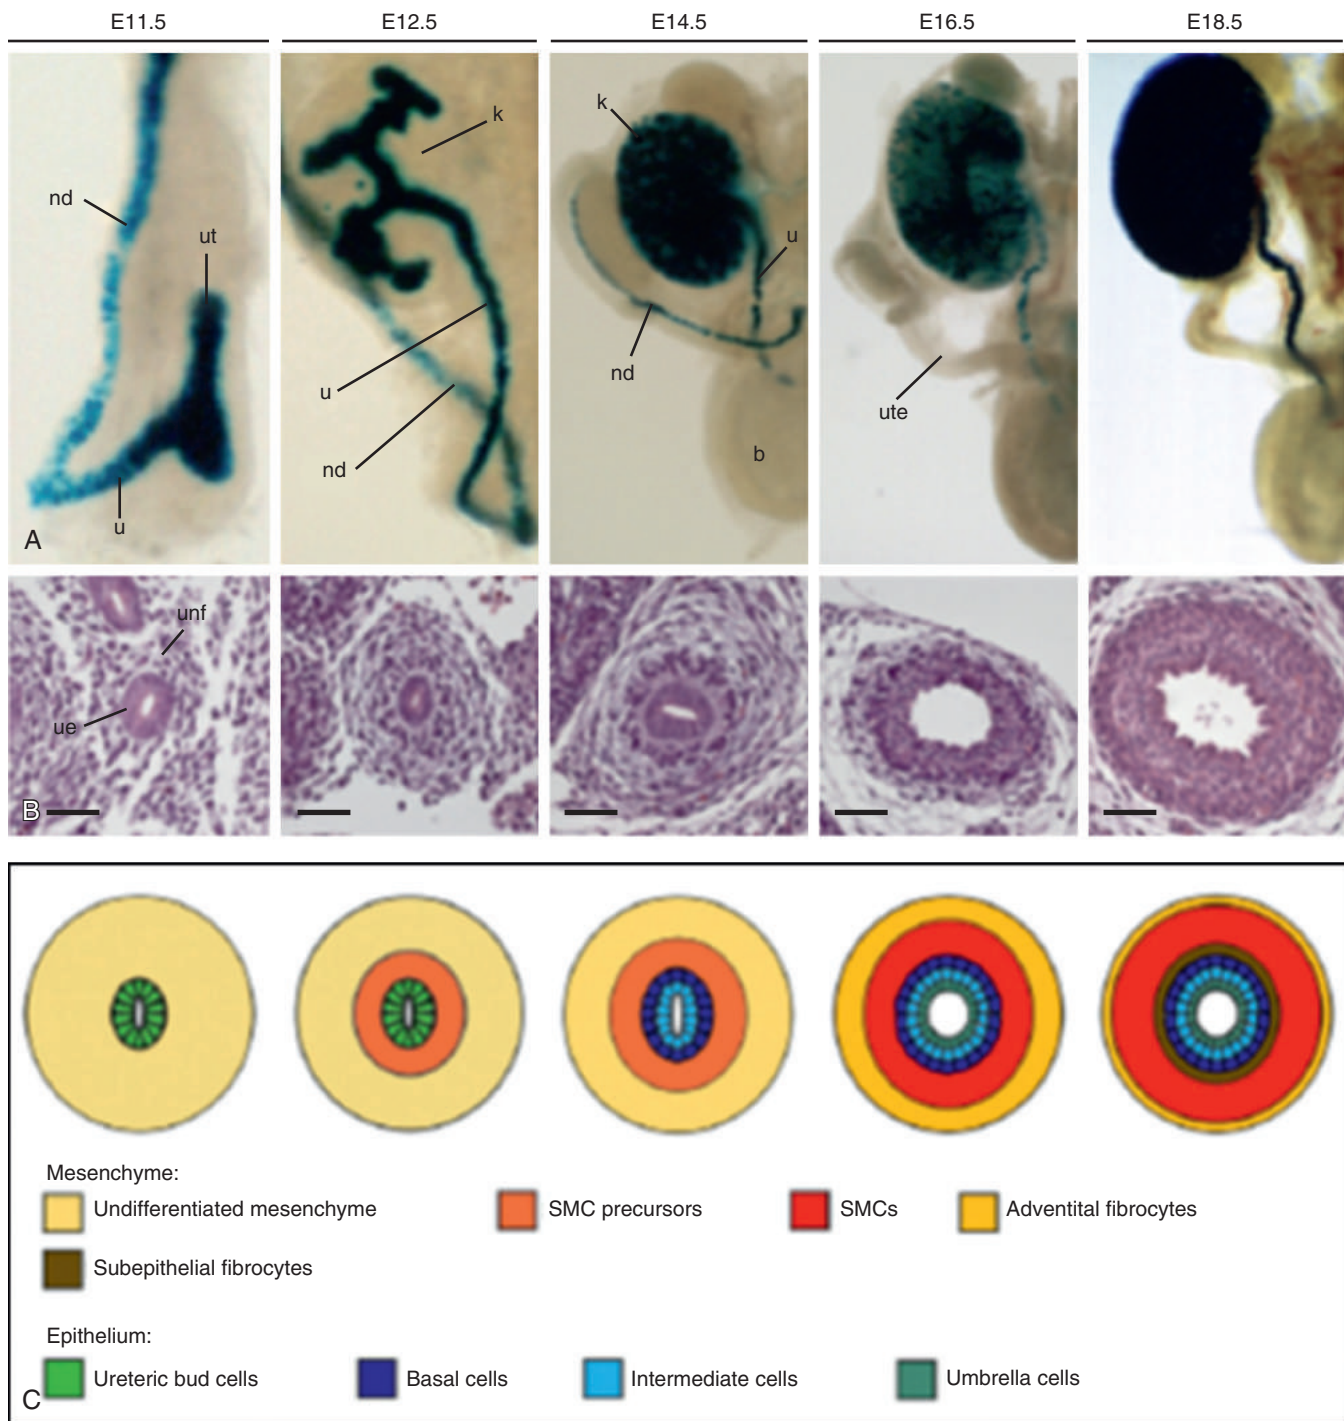

Abnormalities in the smooth muscle function, particularly in the ureteropelvic or ureterovesical junctions, prevent efficient drainage of urine from the renal pelvis to the bladder and can cause either urinary efflux or urinary reflux. Obstruction at either the upper ureter or the lower ureter, with dilation of the ureter (hydronephrosis) or renal pelvis (hydronephrosis), can cause damage to the renal parenchyma, with marked decrease or even absence of function if obstruction is particularly severe. These conditions comprise a large subset of congenital anomalies of the kidney and urinary tract and are frequent manifestations of underlying genetic defects. Diagnosis of such defects is now frequently made before birth with prenatal ultrasound imaging (Bohnenpoll and Kispert, 2014).

The ureters arise from the nephric duct as do the metanephric kidneys. The ureteral bud evaginates from the nephric duct and, ultimately through extensive branching and elongation, becomes the ducting system ending with the collecting ducts in the kidney, while the stalk portion of the ureteral bud becomes the epithelial portion of the ureter. In the human, starting on embryonic day E12.5, the distal end of the stalk separates from the nephric duct to integrate into the urinary bladder and separate from the genital tube structures. Urine production starts around E16.5, by which time the epithelium around the ureteral stalk differentiates into urothelium. The development of the smooth muscle layer starts around E13.5 to E15.5.

The development of the ureter depends on ureteral bud development and on GDNF binding to RET, which activates the formation of the endothelium from the tissue near the nephric duct. If the GDNF signaling is anterior or posterior to the normal placement of the ureteral bud, the ureters may develop ectopically in the bladder or urethra (Bohnenpoll and Kispert, 2014). The primordial ureters that arose from the nephric duct will differentiate into the vas deferens in the male, while they degenerate in the female.

To remain patent, the ureter must translocate from the nephric duct into the developing bladder wall in the cloaca. The first step occurs when the nephric duct fuses to the cloaca. This may occur from mutual signaling between the nephric duct to the cloaca; however, the precise mechanisms are poorly understood. In the second step, the distal part of the ureter is incorporated into the bladder wall, where it undergoes apoptosis until the ureter is placed in its final position on the bladder trigone. If there is aberrant distal ureteral maturation, the ureter will end blindly inside or outside the bladder as a ureterocele or an ectopically located ureter in the bladder, urethra, or other ectopic location along the genitourinary tract following the path of the involuting nephric duct. These ureters are hydronephrotic.

Further formation of the proximal, mid, and distal parts of the ureter depends on the local epithelia and mesenchyme tissue in the region of that portion of the developing ureter. The mesenchyme near the distal ureteral stalk will elongate, while the same mesenchyme transplanted to the proximal ureteral region will branch and induce nephrogenic aggregates that will lead to nephron-like structures. The signaling molecule for distal ureteral development through mesenchymal specialization is likely BMP4. Absence of or a decrease in the level of BMP4 leads to ectopic budding of the nephric duct and the distal ureteral stalk. In the human, by E12, experiments on explant metanephric cell cultures have shown that the ureteral mesenchyme is radially arrayed with connective

tissue and smooth muscle cells that depend on the adjacent epithelium to develop as the distal ureter. Signaling by sonic hedgehog (Shh) expressed by the ureteral epithelium at E11.5 to E18.5 also stimulates development of the ureter by increasing mesenchymal growth of the ureter. BMP4 appears to stimulate Shh to help

differentiate the smooth muscle cells into the developing ureter (Fig. 86.7).

At E16.5, terminally differentiated smooth muscle cells with abundant contractile filaments are located all along the developing ureter. These muscle fibers are tightly packed and interconnected

with gap junctions, causing smooth muscle contractions to be propagated in proximal to distal waves. The waves are coordinated and are preceded by spontaneous electrical activity in the renal pelvis. This is independent of nerve function or stimulation (Bohnenpoll and Kispert, 2014). The smooth muscle cells in this region show spontaneous oscillations of a membrane potential that spreads to the other smooth muscle cells and generates the wave down the ureter to the distal part of the ureter (Fig. 86.8).

The urothelium itself is highly specialized stratified epithelium, which is the inner lining of the urinary drainage system from the renal pelvis to the proximal part of the urethra. The derivation of the epithelium in the bladder is endoderm in nature, while the ureteral epithelium is mesodermal in origin. It is uncertain if the development of this urothelium from the different origins is the same for the bladder as the ureter, but ureteral development lags that of bladder development.

Renin–Angiotensin System Interaction for Programing Fetal Development

The RAS is a systemic hormonal process mediating sodium reabsorption, vasoconstriction, aldosterone production, and vasopressin secretion. Angiotensinogen is produced by the liver and activated by renin (from the kidney) to form angiotensin I. Angiotensin II is cleaved by angiotensin-converting enzyme (ACE) to create angiotensin II, which is the most biologically active peptide.

Angiotensin II acts on the angiotensin type 1 (AT1) and angiotensin type 2 (AT2) receptors. Beyond the circulating RAS, there is also a local RAS in many other organs, including the kidney and the placenta, which will act as an autocrine or a paracrine agent (Moritz et al., 2010). The RAS plays a critical role in the growth, development, and functioning of many organs. These include the kidney and the placenta. During renal angiogenesis, angiotensin II acting on AT1 receptors mediates renal tubular growth and branching. AT2 receptors in the fetal kidney act as a growth mediator to prevent uncontrolled renal tubule growth through apoptosis. The uteroplacental circulation has a local RAS

that aids in placental angiogenesis and modulates placental cytokine, growth factor, and vasoactive substance production, which all affect fetal growth and development. Angiotensin II–stimulated AT1 receptor activity promotes trophoblast invasion, angiogenesis, growth, and branching of the placenta, while also regulating vasoconstriction in the uterine spiral arteries. Additionally, AT1 receptors have been found in the chorionic villi, showing regulation of function of fetal blood flow within the placenta.

Studies have shown that sex hormones differentially regulate the RAS pathway: testosterone increases the expression of renin and AT1 receptor with upregulation of the vasopressor arm, and estrogens increase the upregulation of the vasodepressor arm (ACE2 and AT2 receptor) (Moritz et al., 2010). The renal RAS and the placental RAS may be differentially expressed in male and female tissues, may respond differently to adverse stimuli, and may result in differences in adult males and females.

Prenatal exposure of the fetus to excessive glucocorticoids may have adverse effects. Glucocorticoids are potent regulators of fetal growth and development. Maternal glucocorticoid exposure can reduce nephron endowment and alter expression of the RAS in fetal kidneys. Studies in sheep, rats, and spiny mice have shown that even a short-term, early-gestation exposure of the fetus to dexamethasone infusions can decrease the number of nephrons.

Fetal Programing of Renal Function and Perinatal Environmental Factors Influence Development of Renal Function and Adult Renal Disease

Genetic and environmental factors are important determinants of the development and function of the major organ systems of the body. It is becoming more and more evident that prenatal programing can affect subsequent organ function and some adult diseases. Brenner has studied the effects of fetal programming on the kidney and its subsequent risks for development of hypertension and renal disease in adulthood. LBW, as defined as birthweight less than 2500 g, has been associated with high incidence of cardiovascular disease, diabetes, hypertension, and renal disease. The risk of intrauterine growth restriction (IUGR) and LBW is twice as high in African Americans as in white populations. Risk factors for IUGR and LBW are consistently found more often in certain populations. For example, fetuses with higher risk of IUGR and LBW include those of African-American or Asian origin as well as those exposed to maternal hypertension, maternal smoking, inadequate maternal weight gain or malnutrition, shorter maternal height, poor prenatal care, advanced maternal age, and lower socioeconomic status.

Animal models have shown that LBW is associated with later development of hypertension. The hypertension may be due to lower nephron numbers frequently seen with IUGR. Additionally, LBW adversely affects RAS activity. Brenner hypothesized that low nephron numbers at birth result in decreased filtration surface area, limiting renal sodium excretion, causing an increased risk of development of essential hypertension.

Human studies have also found an inverse relationship between LBW and higher blood pressures in infancy through adulthood. Although not all children with LBW have hypertension, the blood pressure measurements in these infants, children, and young adults tend to be higher than those of normal birthweight individuals. High birthweight (>4000 g) has also been associated with adverse

renal outcomes in later life. It is uncertain in humans if there is any relationship with abnormal nephron number (Luyckx et al., 2011). LBW infants also have an increased adult risk of coronary heart disease, insulin sensitivity, and hypertension. Females have approximately 12% fewer glomeruli than males. After 18 years of age, the kidneys lose approximately 3676 nephrons per kidney per year. Adult height also has a positive correlation with the number of nephrons an individual may have: for each centimeter increase in height, there are about 28,000 more glomeruli. Height was also found to contribute about two-thirds of the variance in glomerular number.

The numbers of nephrons are determined before birth, but the kidney can increase filtration capacity by hypertrophy of the glomerulus (Luyckx and Brenner, 2005; Luyckx et al., 2011). Mean glomerular volumes correlate inversely with glomerular numbers but directly with current body size. Hypertensive individuals have a 133% higher mean glomerular volume but a 46.6% reduction in glomerular numbers compared with nonhypertensive controls.

Perinatal programing controls nephrogenesis from early fetal development until 34–36 weeks' gestation, at which time the full nephron development is complete. If an infant is born before 36 weeks' gestation, nephrogenesis is still ongoing, but the number of nephrons produced may be reduced because of intrauterine stress or prenatal/perinatal stressors on development. Potential perinatal programming for hypertension and diabetes may be associated with the development of chronic kidney disease because of total nephron number reduction (Puddu et al., 2009).

Barker speculated that maternal intrauterine factors may affect prenatal development of the various fetal organ systems that will ultimately affect the function of those systems into adulthood. "Barker's hypothesis" is best demonstrated by the prenatal programming of ultimate adult development of hypertension and cardiovascular disease found in LBW infants who have a lower nephron number because of adverse maternal factors transmitted to the fetus during nephrogenesis. Barker further suggested that there is variance in gene expression during development that may be caused by different in utero conditions to which the fetus is exposed. The most critical times for fetal programming with either normal or abnormal expression are during periods of rapid cell migration, division, and differentiation. The critical programing time for human renal development is between weeks 31 and 36, as nephrogenesis is completed by week 36 (Koleganova et al., 2009).

Diabetes is the world's leading cause for end-stage renal disease. Unfortunately, LBW also has an association with development of pancreatic insufficiency and development of diabetes. In studies in monozygotic twins, the lower birthweight infant had a higher risk of developing diabetes later in life than the normal birthweight infant. The risk is highest in those LBW infants who caught up the fastest in weight. The proposed explanation for this finding is that the LBW or undernourished infant resets its insulin hormone axis to adapt to increased growth when needed for development in utero, and this upregulated metabolism may not correct itself once the infant has caught up in growth (Luyckx and Brenner, 2005).

Kidney volume is dependent on nephron number and can be measured by ultrasound testing. Young adults with a history of prematurity, regardless of their birth size, have smaller kidneys than term-matched controls, and even the effect of IUGR on kidney size as a young adult was not significant (Luyckx et al., 2011). Genetic and environmental factors can cause a reduction in total nephron number. This interaction between genetic

programing and environmental factors influences renal function potential from fetal life to adulthood.

Small for gestational age (SGA) infants have a shorter renal length than normal-sized infants, and, with aging, the kidneys of the SGA infant demonstrate either accelerated renal maturation or early compensatory kidney hypertrophy. Under the hyperfiltration hypothesis, hypertrophy of glomeruli may predispose the individual to development of hyperperfusion injury of the tubules, which then leads to deterioration of renal function and development of proteinuria, glomerulosclerosis, and tubular and interstitial inflammation and fibrosis (Puddu et al., 2009).

The kidney is central in regulating blood pressure and is implicit in causing hypertension. The kidney's regulation of sodium homeostasis, intravascular fluid regulation, and regulation of solute filtering is part of renal regulation of blood pressure and is why the kidney is implicated in development of hypertension when these functions do not occur appropriately. Other risk factors for the development of hypertension and renal disease are a family history of the same renal problems, hypertension, diabetes, obesity, gestational diabetes, dietary factors, insulin resistance, and being a member of certain otherwise at-risk ethnic groups.

Malnutrition of the mother through low protein intake during intrauterine and neonatal life may have an adverse effect on renal function; ongoing renal damage is caused by continued high salt intake and an unbalanced fat and protein diet later in life. The developing kidney may also be adversely affected by vitamin A deficiency, urinary tract malformation with obstruction or infection, and exposure to nephrotoxic drugs (antibiotics, nonsteroidal antiinflammatory drugs [NSAIDs]). Other fetoplacental factors causing a decrease in the necessary nutrients by restricting their transfer include maternal smoking, hypertension, poor nutrition, and socioeconomic factors affecting nutrition. Additionally, IUGR may be caused by decreasing available intrauterine space through primiparity, low maternal height, and being a mother who was also an SGA baby (Puddu et al., 2009).

Perinatal obstructive uropathy may cause reduced nephron numbers in the affected individual. The diminution of nephrons with obstruction may be due to mechanical stretching of the tubules, which in turn activates ion channels that increase intracellular calcium levels and, subsequently, cellular apoptosis (Puddu et al., 2009). In animal models with unilateral ureteral obstruction with subsequent relief of the obstruction, the major damage found was due to tubular apoptosis and atrophy causing subsequent impaired growth of the postobstructed kidney, reduced glomerular numbers, and decreased GFR. The uninvolved kidney will show compensatory growth, but both kidneys will show glomerular sclerosis, tubular atrophy, macrophage infiltration, and interstitial fibrosis. Urinary obstruction in adults does not appear to cause reduction in the nephron number that is seen in congenital or perinatal obstruction. There may possibly be an increased vulnerability of the nephrons to damage with obstruction occurring during or just after completion of nephrogenesis. High-grade vesicoureteral reflux diagnosed shortly after birth may also be associated with poor renal outcome. Unfortunately, early postnatal diagnosis and treatment did not improve the renal outcomes in this group of patients either (Puddu et al., 2009).

Vitamin A has been found to determine fetal renal programming in rats through modulation of nephron number and vascular supply to the developing kidney. Vitamin A and other retinoids help regulate cell proliferation, differentiation, immune function, and apoptosis. These animal findings provide indirect evidence of the importance of vitamin A in human kidney development. Low

circulating levels of vitamin A are common in women who are smokers, abuse alcohol, or have poor perinatal nutrition, which may cause low or absent vitamin A levels in the developing fetus and is associated with IUGR in infants.

Maternal intake of nephrotoxic drugs during pregnancy has also been associated with neonatal development of acute renal failure, especially in preterm or LBW infants. It is postulated that maternal exposure to NSAIDs may cause hypoperfusion of the kidneys and fetal nephrotoxicity from vasomotor nephropathy due to decreased levels of prostaglandin E_2 . There appears to be less damage to the newborn kidney with NSAID exposure suggesting that the risk of damage is highest during nephrogenesis itself.

Treatment of children with low renal reserve who have hypertension or hyperalbuminuria with ACE inhibitors may have a renal protective role through reducing angiotensin II–modulated cellular apoptosis and decreased renal tubular and interstitial fibrosis. However, use of ACE inhibitors is not without risks to kidney function as they have been found to cause hypotension, oliguria, hyperkalemia, acute renal failure, and reduced glomerular filtration, especially in patients with bilateral renal artery stenosis.

Although low nephron number is associated with renal disease and hypertension, not all renal programming models show this; some studies have found associated hypotension. Some ethnic groups, for example, African Americans, with decreased nephron numbers have not exhibited associated hypertension. Some other as yet undetermined factors may be required to induce hypertension and renal disease. Some factors that may or may not have an association with low nephron number and hypertension/renal disease may include individual genetics, including the sex of the individual, with less hypertension generally seen in premenopausal females with decreased nephron numbers. Sex differences in arterial pressure may be due to sex hormones as well as sex chromosomal complement. Female fetuses also appear to be less vulnerable to adverse in utero environmental factors than male fetuses (Kett and Denton, 2011).

Some modifiable risk factors such as diet and stress may improve or worsen ultimate renal outcome. Limited human studies have shown a higher sensitivity to dietary salt intake with respect to high blood pressure development in adults with a history of LBW as compared with normal birthweight adults. This salt sensitivity for blood pressure has also been found in studies of children. Animal studies have shown that salt sensitivity can be modulated early in life if a low-salt diet is instituted (Kett and Denton, 2011).

Early renal programming studies in animals demonstrated an increase in systemic blood pressure when there was in utero exposure to a low-protein maternal diet, malnutrition, or dexamethasone. More recent studies have found that the resting blood pressure in these animals is not different from the same resting pressures in controls. Blood pressure elevations appeared to be related to secondary stressors being present. Historic human studies using the Dutch Famine cohort found that the baseline blood pressures were similar between those exposed to famine and those who were not. Blood pressure elevations were higher in famine-exposed groups when they had additional stress, especially if they were exposed to famine early in gestation (Kett and Denton, 2011).

Although fetal renal programming may put the LBW, IUGR, and individuals with in utero environmental exposure to renal damaging factors at risk of hypertension and poor renal function as an adult, there appears to be a significant ability of the kidney

to compensate for these prenatal insults to normal renal development. By control of secondary risk factors such as diet and stress in the adult, there is the possibility of reducing adverse outcomes (hypertension and renal insufficiency) because of abnormal renal developmental (Kett and Denton, 2011).

Conclusion

Renal organogenesis is a complex process that is not yet fully understood but has complementary interactions stimulated by anchor genes, activator molecules, growth factors, and hormone effects. Environmental factors in the maternal–placental–fetal interface are being further elucidated, with implications in adverse adult health outcomes, but some of these may be offset by modification of secondary factors.

Developmental Abnormalities of the Kidneys

RACHEL ENGEN AND SANGEETA HINGORANI

KEY POINTS

- Renal malformations account for 20%–30% of all prenatally diagnosed developmental anomalies and are responsible for 31% of all childhood end-stage renal disease.
- Patients with unilateral renal agenesis are at risk for hypertension in childhood and chronic kidney disease in adulthood.
- Multicystic dysplastic kidney typically presents as a collection of large renal cysts on ultrasound, and patients generally do well. Autosomal recessive polycystic kidney disease presents as bilaterally enlarged hyperechoic kidneys, often without cysts, and patients may have significant pulmonary and renal complications.
- The outcome for patients with renal dysplasia depends significantly on the amount of functioning renal tissue and the associated congenital anomalies.
- Infant dialysis has improved rapidly over recent years, and 2-year survival outcomes as high as 80% are now reported by multinational dialysis databases.

Normal renal development begins with two precursor organs, the pronephros and mesonephros, followed by the definitive metanephros at approximately 5 weeks' gestation. The metanephros develops from an interaction between a branch of the mesonephric (Wolffian) duct, called the ureteric bud, and the surrounding metanephric mesenchyme. The repeatedly branching ureteric bud will become the collecting system, including the collecting ducts, renal pelvis, ureter, and bladder trigone. The metanephric mesenchyme will form the glomerular podocytes, proximal tubule, loop of Henle, and distal convoluted tubule. Nephrogenesis begins at 9 weeks' gestation and is complete by 32–36 weeks' gestation. A complex and carefully timed web of signaling “crosstalk” between the mesonephric duct, metanephric mesenchyme, and surrounding tissue is necessary to coordinate proper renal development. Any interruption of this process can lead to abnormalities in kidney structure and function (Reidy and Rosenblum, 2009).

Developmental abnormalities of the kidney and the urinary tract affect 3–6 per 1000 births (Sanna-Cherchi et al., 2007) and account for 31% of all children with end-stage renal disease (ESRD) in the United States (Reidy and Rosenblum, 2009). Renal malformations represent 20%–30% of all prenatally diagnosed developmental

anomalies; prenatal ultrasound allows malformations that are asymptomatic at birth to be detected. Long-term outcomes for children with development anomalies of the kidney depend on the amount of functional renal tissue at birth, associated urinary tract anomalies, degree of prematurity, urine output, and presence of additional congenital anomalies.

With advances in neonatal critical care, nutritional therapy, and peritoneal dialysis techniques, many children who previously would have died in early infancy are surviving, growing, and receiving a renal transplant. Reviews of multinational dialysis databases have reported 2-year survival rates as high as 80% in infants who start dialysis (van Stralen et al., 2014). Successful provision of care requires a multidisciplinary team approach that includes the neonatologist or pediatrician, nephrologist, surgeon, urologist, nutritionist, nurse, and social worker. Above all, it requires close communication with and strong support of the child's family, who may bear enormous emotional and financial burdens in caring for their child.

Abnormalities of Kidney Number

Unilateral Renal Agenesis

Unilateral renal agenesis, or a congenital solitary kidney, results from a unilateral early and complete failure in the signaling interaction between the ureteric bud and metanephric mesenchyme. The estimated incidence is 1 in 500 to 1 in 1000 children (Shapiro et al., 2003). Approximately 30%–40% of children with unilateral renal agenesis will have other developmental anomalies; roughly 25% will have vesicoureteral reflux with the remainder having ureter–pelvic junction obstruction and gastrointestinal, cardiac, and musculoskeletal anomalies (Westland et al., 2013). The same embryologic insult that led to failure of kidney development can also cause abnormalities of other mesonephric duct derivatives, including the seminal vesicles, vas deferens, and epididymis (Shapiro et al., 2003) and Müllerian duct organs. Approximately 50% of girls with unilateral renal agenesis will have genital tract abnormalities, including unicornate or didelphic uterus and vaginal obstruction (Hollander et al., 2008).

Renal agenesis was once thought to be a benign condition if the contralateral kidney appeared healthy. However, there is now increasing concern that unilateral renal agenesis increases the risk

TABLE 87.1 Syndromes With Renal Agenesis and Ectopia

Data from Zenteno et al., 1999; Keppler-Noreuil, 2001; Greenhalgh et al., 2002; Massin et al., 2003; Oppelt et al., 2012; Barisic et al., 2013; Bernardo et al., 2015; Rall et al., 2015.

for chronic kidney disease in adulthood (Chevalier, 2009; Sanna-Cherchi et al., 2009). The “hyperfiltration” hypothesis suggests that compensatory hyperfiltration in the healthy kidney leads to single-nephron hypertension, glomerulosclerosis, and nephron loss over time (Brenner et al., 1996). Recent studies of outcomes for children with congenital solitary kidney identified proteinuria and hypertension in 5%–25% of patients during childhood (Vu et al., 2008; Westland et al., 2011), while chronic kidney disease affects approximately 13%–30% of adults with a solitary kidney (Shapiro et al., 2003; Vu et al., 2008). The presence of other urinary tract abnormalities or any dysplasia in the remaining kidney worsens the prognosis.

Unilateral renal agenesis is asymptomatic in infants with a healthy contralateral kidney. The routine use of voiding cystourethrogram to screen for vesicoureteral reflux in infants without evidence of a urinary tract infection is now controversial. Children with unilateral renal agenesis should be monitored for appropriate compensatory hypertrophy of the healthy kidney during infancy and should have annual screening for proteinuria and hypertension during childhood (Vu et al., 2008). Girls with a solitary kidney should be screened for uterine abnormalities before puberty (Hollander et al., 2008; Table 87.1).

Bilateral Renal Agenesis

Bilateral renal agenesis occurs in 1 in 3000 births. It may be an isolated finding or part of a syndrome, such as the brachio-oto-renal

dysplasia syndrome or a hereditary renal adysplasia. It is typically diagnosed prenatally in a pregnancy complicated by severe oligohydramnios or anhydramnios and nonvisualization of the fetal kidneys and bladder. Bilateral renal agenesis is responsible for approximately 20% of cases of the oligohydramnios sequence (Potter syndrome) (Elder, 2016), in which decreased amniotic fluid causes compression of the fetus. Patients have the classic low-set ears, wide-set eyes with epicanthal folds, flat nose, and receding chin (Fig. 87.1). Infants are typically born alive but die within the first hours to days of life because of pulmonary hypoplasia. There is one case report of treatment with serial amniotransfusion that resulted in the birth of an infant who survived with minimal respiratory support (Bienstock et al., 2014).

Abnormalities of Renal Position

Ectopic Kidney

Renal ectopia occurs when the kidney fails to ascend from its embryologic position in the fetal pelvis to its final position in the renal fossa. Ectopia can be simple, with the kidney located ipsilateral to its uterine insertion, or crossed, with the kidney located contralaterally. Crossed ectopic kidneys typically fuse to the orthotopic kidney (van den Bosch et al., 2010). Approximately 20%–30% of patients will have vesicoureteral reflux usually into the orthotopic kidney (Guarino et al., 2004; van den Bosch et al., 2010). It is found in 1 in 1000 individuals on autopsy and is typically

asymptomatic; approximately 90% of patients are never diagnosed. Ectopia is not associated with hypertension, proteinuria, or chronic kidney disease. Patients are typically not followed closely if there is no evidence of reflux or obstruction.

Horseshoe Kidney

A horseshoe kidney occurs when the two kidneys are fused, typically at the lower poles, by a parenchymal or fibrous isthmus. This fusion impedes the embryologic ascent of the horseshoe kidney

• **Fig. 87.1** Potter Syndrome. Potter syndrome facies with low-set ears, wide-spaced eyes with epicanthal folds, flattened nose, and receding chin. (Courtesy of Dr. Laura Finn, Seattle Children's Hospital, Department of Pathology, Seattle, Washington.)

past the origin of the inferior mesenteric artery. It occurs in 1 in 400 children. Twenty-two percent of cases are associated with other systemic abnormalities, including vertebral anomalies, anorectal malformations, and Turner syndrome, and 20%–30% of children will have vesicoureteral reflux. Urinary tract infections and renal stones are common. The risk of progression to chronic kidney disease is primarily dependent on the amount of kidney damage suggested by proteinuria, hypertension, and renal scarring (Yavuz et al., 2015).

Abnormalities of Renal Organization

Multicystic Dysplastic Kidney

A multicystic dysplastic kidney (MCDK) develops when there is an impairment of nephrogenesis, resulting in branched ducts surrounded by connective tissue and undifferentiated cells. Occasionally there will be areas of recognizable renal tissue, but the ureter is not patent and the kidney is nonfunctional (Schreuder et al., 2009). MCDK is typically a sporadic and unilateral finding that occurs in 1 in 4300 births. It is the second most common cause of a flank mass in newborns. MCDK can be accurately diagnosed on ultrasound as a collection of large cysts that do not communicate with the renal pelvis (Kerecuk et al., 2008); a nuclear medicine scan is not necessary for diagnosis (Sarhan et al., 2014; Whittam et al., 2014) (Fig. 87.2).

Approximately 20% of patients with MCDK have vesicoureteral reflux in the contralateral kidney; 40% of these children will have severe (grade III–V) reflux (Schreuder et al., 2009). However, given the low rate of clinical intervention in some recent cohorts, the need for routine screening voiding cystourethrogram (VCUG) is controversial. If VCUG is not performed, the parents should be given instructions on monitoring for urinary tract infections (Calaway et al., 2014). Five percent of MCDKs are associated with a contralateral ureteropelvic or ureterovesical junction obstruction; approximately 15% will have other developmental abnormalities (Schreuder et al., 2009).

• **Fig. 87.2** Multicystic Dysplastic Kidney. (A) Gross pathology specimen of a multicystic dysplastic kidney. (B) Prenatal ultrasound image of a multicystic dysplastic kidney. Note the many large cysts. (A, Courtesy of Dr. Laura Finn, Seattle Children's Hospital, Department of Pathology, Seattle, Washington; B, Courtesy of Jennifer McBroom, Seattle Children's Hospital, Department of Radiology, Seattle, Washington.)

Multicystic dysplastic kidneys undergo spontaneous involution over time, with 5% of prenatally detected MCDKs no longer visible at birth and 40%–55% involuted by age 5 years. If the contralateral kidney is normal, MCDK is usually asymptomatic, with a prognosis similar to unilateral renal agenesis (see earlier). In rare cases MCDK may be a bilateral finding; these infants generally die soon after birth because of pulmonary hypoplasia. Patients should have routine ultrasound monitoring in infancy to ensure involution of the MCDK and appropriate compensatory hypertrophy of the contralateral kidney, with annual screening throughout childhood for hypertension and proteinuria. Nephrectomy is generally only performed if there is a clear indication. Older studies associated MCDK with an increased incidence of Wilms tumor, but more recent cohorts have not found an association (Eickmeyer et al., 2014; Moralioglu et al., 2014). Currently, there is no routine tumor monitoring recommended for MCDK.

Isolated Renal Dysplasia

Renal dysplasia occurs when either failure of ureteric bud-metanephric mesenchyme signaling or early urinary flow obstruction disrupts the normal development and differentiation of the fetal kidney (Chen and Chang, 2015). The tissue is made up of primitive ducts, branches of the ureteric bud, surrounded by a ring of fibromuscular tissue and disorganized lobar development (Kakkar et al., 2006). Renal dysplasia may be unilateral or bilateral, isolated or syndromic, and sporadic or genetic. Mutations in *ITGA8*, an integrin important to cell structure and signaling, and *FGF20*, a fibroblast growth factor with a variety of functions in growth and development, have been associated with dysplasia and/or agenesis. Renal dysplasia occurs in 0.1%–3% of births and is the most common cause of childhood ESRD (Chen and Chang, 2015).

Renal dysplasia is typically diagnosed prenatally or postnatally with the appearance of large, bright kidneys on ultrasound. Cysts may or may not be present. Treatment and prognosis depend on the degree of dysplasia and associated findings. Children with unilateral renal dysplasia and a normal contralateral kidney may have outcomes similar to children with unilateral renal agenesis. Children with bilateral renal dysplasia have variable outcomes depending on the degree of residual renal function. Mild bilateral dysplasia may result in adequate amniotic fluid production for lung development; however, generally, there is a progressive decline in renal function in infancy or childhood. Severe bilateral dysplasia has significantly worse postnatal outcomes, particularly if children develop the oligohydramnios sequence (Potter syndrome) with pulmonary hypoplasia (Winyard and Chitty, 2008). Treatment may include dialysis, but the appropriateness of dialysis is typically determined on a case-by-case basis after discussion of the multidisciplinary care team and parents.

Prognosis for children with renal dysplasia associated with genetic syndromes often depends on the patient's other developmental abnormalities. Some of the more common syndromes are presented below and in Table 87.2.

Renal Coloboma Syndrome

Renal coloboma syndrome (aka papillorrenal syndrome) is an autosomal dominant disorder caused by mutations in *PAX2*, a transcription factor involved in development. Affected children have optic nerve coloboma (dysplasia) and small dysplastic kidneys (Schimmenti, 2011). Vesicoureteral reflux, high-frequency hearing

loss, and central nervous system anomalies may also be present. Most patients have progressive renal dysfunction, though the timing is highly variable, even in families with the same *PAX2* mutation (Cheong et al., 2007; Schimmenti, 2011).

Brachio–Oto–Renal Syndrome

Branchio–oto–renal syndrome is an autosomal dominant condition affecting 1 in 40,000 newborns. It is caused by mutations in *EYA1*, *SIX1*, or *SIX5*, which interact in the development of the branchial arches, inner ear, and kidney (Bertucci et al., 2015). Clinical manifestations include branchial arch anomalies (clefts, fistula, cysts), preauricular pits, hearing impairment (conductive or sensorineural), and renal anomalies ranging from unilateral dysplasia to bilateral agenesis (Kochhar et al., 2007).

Hypothyroidism–Deafness–Renal Dysplasia Syndrome

Hypoparathyroidism–deafness–renal dysplasia syndrome (aka Barakat syndrome) is an autosomal dominant disorder with variable penetrance caused by mutations in *GATA3*, a transcription factor involved in embryologic development (Gaynor et al., 2009). Patients can present at any age with symptomatic hypocalcemia secondary to hypoparathyroidism or early-onset bilateral sensorineural hearing loss that worsens with age. The associated renal abnormalities include unilateral or bilateral renal dysplasia or agenesis, though vesicoureteral reflux, proteinuria, and progressive chronic kidney disease have been described (Maleki et al., 2013; Shim et al., 2015).

VACTERL

The VACTERL association consists of vertebral defects, anal atresia, cardiac anomalies, trachea–esophageal fistula, renal malformations, and limb abnormalities; diagnosis is made by the presence of three of the component features. The genetics of VACTERL are heterogeneous, and many of the currently identified mutations are related to the Sonic hedgehog signaling cascade (Reutter et al., 2016). Renal anomalies are one of the most common component features of VACTERL, found in approximately 65%–80% of affected children, and typically consist of unilateral renal agenesis or dysplasia. There is an increased risk of chronic kidney disease in childhood. Twenty-seven percent of those with renal anomalies and 12% of children without visible renal anomalies will have vesicoureteral reflux (Cunningham et al., 2014).

Eagle–Barrett Syndrome

Eagle–Barrett (prune-belly) syndrome is the triad of deficient abdominal wall musculature, bilateral undescended testes, and urinary tract abnormalities including renal dysplasia and an enlarged, hypotonic bladder (Fig. 87.3). It affects 3.7 per 100,000 live male births; females comprise less than 5% of cases. Cardiac, gastrointestinal, and musculoskeletal abnormalities are common; 10% of children have respiratory insufficiency related to oligohydramnios and pulmonary hypoplasia. Ten to 25% of children die in the neonatal period of respiratory failure or prematurity. Because of poor bladder tone, most patients have vesicoureteral reflux and develop urinary tract infections. Urologic management with intermittent catheterization or surgery is important to allow adequate bladder drainage and preserve renal function. Forty to 50% of children develop chronic kidney disease, and 15% will ultimately

require dialysis or renal transplantation, often before school age (Seidel et al., 2015).

Abnormalities With Renal Overgrowth

Beckwith–Wiedemann syndrome is an overgrowth disorder caused by abnormal methylation in two gene regulation regions, *IC1* and *IC2*. Most cases are sporadic; in rare cases there is autosomal dominant inheritance. Patients are large at birth with hemihyperplasia, abdominal wall defects, enlarged tongues and internal organs, hyperinsulinemic hypoglycemia, *nevus flammeus* capillary malformations, and dysmorphic facial features. Nephromegaly is the most common kidney finding, though renal cysts, nephrolithiasis, and urinary tract malformations have also been reported (Mussa et al., 2012). The kidneys contain nephrogenic rests, areas of embryonic kidney tissue that are at high risk for malignant transformation. Ten percent of patients with Beckwith–Wiedemann syndrome develop embryologic cancers before 10 years of age, and 40%–60% of these cases are Wilms tumor (nephroblastoma). Tumor screening by abdominal ultrasound is recommended for all patients every 3–4 months until age 8 years (Mussa et al., 2015).

Simpson–Golabi–Behmel syndrome is an X-linked condition associated with mutations in *glypican3*, which may be involved in regulating embryologic growth. Affected children have many of the same findings as in Beckwith–Wiedemann syndrome, though hemihypertrophy and *nevus flammeus* are typically absent. There is a similar risk for Wilms tumor, and a similar screening schedule is typically recommended (Knopp et al., 2015).

Perlman syndrome is an autosomal recessive congenital overgrowth disorder caused by mutations in *DIS3L2*, a gene involved in ribonucleic acid processing. Patients are large at birth with poor muscle tone and characteristic facial features. There is often polyhydramnios in utero and nephromegaly. In one case series, 29% of children with Perlman syndrome developed Wilms tumor, half of those tumors were bilateral, and the average age at diagnosis was less than 2 years (Morris et al., 2013). Over half of patients

with Perlman syndrome die of respiratory or renal failure within the first month of life (Alessandri et al., 2008).

Abnormalities Predominated by Renal Cysts

Ciliopathies

Primary cilia are protrusions of the cell membrane overlying a microtubule-based axon core. At the base of the cilium is a basal body, which is one of the two centrioles of the centrosome. Primary cilia sense the extracellular environment and transmit signals to the center of the cell, and they are critical to maintaining coordinated cell polarity (Schwartz et al., 2011). Failure to maintain cell polarity in renal tubular cells results in the development of renal cysts, which is why diverse renal cystic syndromes are now being grouped as ciliopathies. With the exception of a few diseases, including autosomal recessive and autosomal dominant polycystic kidney disease, the ciliopathies are highly heterogeneous genetically. Many syndromes are associated with a dozen or more genes, and single genes are often associated with multiple syndromes depending on the exact mutation and the presence of other cilia gene abnormalities. This genetic diversity can also lead to a high degree of clinical variability within any one syndrome and significant overlap between genetically related syndromes.

Autosomal Recessive Polycystic Kidney Disease

Autosomal recessive polycystic kidney disease (ARPKD) is an autosomal recessive hepatorenal fibrocystic syndrome associated with mutations in *PKHD1*, which encodes a protein of unknown function that localizes to the primary cilia, mitotic spindle, and apical membranes of renal tubule and biliary duct cells. *PKHD1* is expressed in a number of tissues during fetal development, including the ureteric bud, mesonephric tubules, and immature hepatocytes, and probably has a role in organogenesis and tubule formation. In the kidney the abnormality causes dilation of collecting ducts, forming cysts.

ARPKD affects 1 in 20,000 live births, and carrier rates as high as 1:70 have been suggested (Telega et al., 2013). Most patients present at or before birth with enlarged echogenic kidneys with poor corticomedullary differentiation; macrocysts are generally not visible on ultrasound at birth but do develop later in life (Fig. 87.4). Severely affected patients may have the oligohydramnios sequence with pulmonary hypoplasia, but oligohydramnios alone is not predictive of a poor neonatal outcome (Mallett et al., 2015). A small subset of patients present in childhood or adolescence with liver disease.

The kidneys may be so enlarged as to compromise respiratory function after birth, and 20%–30% of affected infants will die due to respiratory insufficiency. The kidneys are often palpable, and the abdomen may be grossly distended. Most patients have abnormal renal function from birth. Hypertension can be severe. As blood flow to the kidney increases after birth, polyuria may develop due to a urinary concentrating defect. All patients with ARPKD have liver disease due to bile duct malformation, and some will develop congenital hepatic fibrosis. Portal hypertension and ascending cholangitis are common complications, and some infants will have fat malabsorption due to abnormal bile flow. The enlarged kidneys may also compress other abdominal organs, further complicating enteral nutrition (Mallett et al., 2015). Hepatic synthetic and metabolic functions generally remain normal until late in the disease course (Telega et al., 2013).

• **Fig. 87.4** Autosomal Recessive Polycystic Kidney Disease. (A) Autosomal recessive polycystic kidney disease. Many microcysts without large cysts. (B) Ultrasound image of an autosomal recessive polycystic kidney measuring 9.1 cm in length, twice the normal length for age. Note the significant increased echogenicity. (A, Courtesy of Dr. Laura Finn, Seattle Children's Hospital, Department of Pathology, Seattle, Washington.)

Initial management is focused on respiratory support and the initiation of peritoneal dialysis, if necessary (Sweeney and Avner, 2011). Polyuric patients require high levels of daily fluid intake to match their excessive urine output, and some may require sodium supplementation (Sweeney and Avner, 2011). Hypertension is often treated with angiotensin-converting enzyme inhibitors (Guay-Woodford, 2014). Infants with fat malabsorption may require supplementation of their fat-soluble vitamins (A, D, E, and K). If the enlarged kidneys are causing respiratory failure, intractable hypertension, or feeding intolerance, bilateral nephrectomy may be performed; however, this necessitates dialysis and may cause hypotension due to the absence of renin production (Mallett et al., 2015).

Approximately 70%–75% of patients with ARPKD survive the newborn period; among those survivors the 15-year survival rate is 67%–79% (Sweeney and Avner, 2011). Over 50% of affected patients require renal replacement therapy, either dialysis or a renal transplant, during childhood, and 7%–10% require a liver transplant (Hoyer, 2015).

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is the most common inherited renal disease, affecting 1 in 500 to 1 in 1000 live births. It is associated with mutations in *PKD1* and *PKD2*, with *PKD1* mutations being more frequent and associated with earlier onset of symptoms. *PKD1* encodes polycystin-1, a membrane protein involved in cell–matrix interactions and possibly calcium homeostasis. *PKD2* encodes polycystin-2, a nonselective cation channel that increases membrane permeability to calcium and interacts physically with polycystin-1 at the primary cilia. ADPKD has an autosomal dominant inheritance pattern but is recessive at the molecular level; it is now generally understood that cells must develop a second, somatic mutation to begin forming a cyst (Sweeney and Avner, 2011).

ADPKD generally presents with bilateral renal cysts in early adulthood followed by progressive cyst development, renal enlargement, hypertension, and renal function decline. Patients may also have cysts in the liver, pancreas, spleen, and seminal vesicles and are at increased risk for vascular abnormalities, including cerebral aneurysms, aortic dilatation, and aortic dissection. Two to five percent of patients with ADPKD present prenatally or in early childhood with symptoms ranging from asymptomatic renal cysts on ultrasound to the oligohydramnios sequence. A history of early-onset ADPKD in a family member portends a high risk of early-onset disease in the patient (Sweeney and Avner, 2011). The majority of infants diagnosed with ADPKD are asymptomatic at birth and remain so throughout childhood. Chronic renal insufficiency has been reported in 8% of children and hypertension in 19% of children by adolescence (Boyer et al., 2007).

It may be difficult to differentiate severe early ADPKD from ARPKD by ultrasound. There are no diagnostic criteria for ADPKD in children less than 15 years old; the kidneys of affected infants may be enlarged, hyperechoic with or without visible cysts, and have increased corticomedullary differentiation. Children rarely have liver or pancreatic cysts, but 10% will have inguinal hernias. Screening the patient's parents for renal cysts may be helpful in determining the correct diagnosis, though normal parental ultrasound does not rule out a diagnosis of ADPKD, as 8%–10% of cases are associated with new mutations.

Tuberous Sclerosis Complex

Tuberous sclerosis complex (TSC) is an autosomal dominant condition associated with mutations in either *TSC1*, encoding hamartin, or *TSC2*, encoding tubulin. *TSC1* and *TSC2* are important regulators of the mechanistic target of rapamycin (mTOR) kinase, a key signaling molecule involved in cell proliferation. Patients develop uncontrolled cellular proliferation, leading to hamartomas of the brain, skin, heart, lungs, and kidneys.

Hypomelanotic skin macules (ash leaf marks) may be the only skin manifestation in infants, and the presence of 3 or more ash leaf marks at birth is suggestive of TSC. Shagreen patches, angiofibromas, and nail fibromas tend to develop later in childhood (DiMario et al., 2015). Seizures and renal angiomyolipomas are common; simple renal cysts are a minor feature of TSC but can be seen. *TSC2* is physically located near *PKD1* on chromosome 16, and 2% of patients with TS will also have ADPKD secondary to a contiguous gene deletion (Rijal et al., 2014). The cysts in ADPKD-TSC appear earlier, are larger, and are more numerous than the simple renal cysts of isolated TSC. Enlarged kidneys also raise the concern for ADPKD-TSC (Back et al., 2015). ESRD is rare in patients with isolated TSC but may occur before age 30 years old in patients with ADPKD-TSC.

Bardet–Biedl Syndrome

Bardet–Biedl syndrome is an autosomal recessive ciliopathy caused by mutations in any of at least 17 genes whose products are involved in the “BBsome,” a complex involved in signaling receptor trafficking to the primary cilia. It affects 1 in 125,000 to 1 in 175,000 children. The abnormal primary cilia signal trafficking that leads to nonspecific glomerular and tubulointerstitial changes in the kidney, with or without renal cysts, and reduced nephron mass. Retinitis pigmentosa, obesity, renal anomalies, learning disabilities, polydactyly, and hypogonadism are the cardinal features (Scheidecker et al., 2014). Hearing loss, developmental or behavioral problems, diabetes, hypertension, cardiac defects, and limb anomalies have also been reported.

Renal anomalies may be both structural and functional. Fetal ultrasound may show enlarged hyperechoic kidneys without corticomedullary differentiation. Cysts and abnormalities of the renal pyramids may be seen. By 3 months of age there is inversion of the corticomedullary differentiation with a hyperechoic medulla. Renal size normalizes over time, and renal cysts may disappear. In childhood, one-third of patients will have polyuria and polydipsia; renal tubular acidosis and other signs of tubular dysfunction are less commonly seen. Hypertension is also common. Approximately 10% of children will develop ESRD, and 25% will require dialysis or transplant by 40 years of age (Putoux et al., 2012).

Jeune Syndrome

Jeune syndrome, also called asphyxiating thoracic dystrophy, is an autosomal recessive skeletal ciliopathy affecting 1 in 126,000 live births and is associated with mutations in a large number of genes, including *IFT80*, *DYNC2H1*, *WDR19*, and *TTC21B*, that are involved in transport along the axon of primary cilia. Since 2006 it has been considered one of the short-rib thoracic dysplasias. Patients have characteristic skeletal abnormalities, including a small narrow chest with short ribs, short squared iliac wings, and short digits and extremities that can typically be diagnosed on prenatal ultrasound. Liver and eye abnormalities may be present. Approximately 40% of patients will have renal anomalies, including cystic dysplasia, renal hypoplasia, or hydronephrosis causing a tubulointerstitial nephropathy and tubular dysfunction.

The abnormal chest development in Jeune syndrome prevents the intercostal muscles from contributing to respiration, and half of children with Jeune syndrome die before 6 months of age secondary to respiratory failure. Surgical techniques for chest wall reconstruction are currently being explored. In limited case series, outcomes appear good if surgery is performed after 1 year of age

but demonstrate 50% mortality before 1 year of age (Betz et al., 2008). If affected children have mild respiratory involvement and live past infancy, they develop a urinary concentrating defect, polyuria, and polydipsia. After 3 years of age renal failure is the leading cause of death among children with Jeune syndrome (Poyner and Bradshaw, 2013).

Nephronophthisis

Nephronophthisis is an autosomal recessive ciliopathy associated with at least 14 different genes involved in primary cilia structure and function, the most common being *NPHP1*. Nephronophthisis is a tubulointerstitial nephropathy with tubular atrophy, corticomedullary cysts, and interstitial fibrosis that presents as polydipsia and polyuria around age 6 years, progressing to renal failure in early adolescence. Infantile nephronophthisis progresses to ESRD around 1 year of age. It has similar pathologic findings as polycystic kidney disease, including cysts seen throughout enlarged kidneys (Wolf and Hildebrandt, 2011), and is typically associated with mutations in *NPHP2* and *NPHP3* (Sun et al., 2016). It has been reported in isolation but is more common as a component of a number of genetic syndromes, including Meckel–Gruber syndrome, Joubert syndrome, and the Joubert-related disorders.

Meckel–Gruber Syndrome

Meckel–Gruber syndrome is an autosomal recessive disorder associated with mutations in any of at least 11 genes, all of which are associated with proper functioning of the primary cilia. It occurs in 2.6 per 100,000 live births and is more common if there is parental consanguinity. Patients have the characteristic triad of bilateral renal cystic dysplasia, occipital encephalocele, and polydactyly. Hepatic fibrosis may also be present. Over 90% of cases are diagnosed prenatally by ultrasound, and 80% of cases result in fetal death or termination of pregnancy. Outcomes are poor; only about one-third of patients survive the first week of life, and the longest recorded survival is 28 months (Barisic et al., 2015).

Joubert Syndrome and Joubert-Related Disorders

Joubert syndrome is an autosomal recessive disorder associated with mutations in any of 25 genes that are associated with the primary cilia and basal body. Patients have developmental delay, hypotonia, an irregular neonatal breathing pattern (episodic apnea and/or tachypnea), and abnormal eye movements including nystagmus and oculomotor apraxia. Facial features may be dysmorphic with a broad forehead, arched eyebrows, ptosis, wide-spaced eyes, and polydactyly. Magnetic resonance imaging shows the characteristic “molar tooth sign,” an unusual combination of cerebellar vermis hypoplasia/dysplasia, elongated superior cerebellar peduncles, and a deep interpeduncular fossa. The molar tooth sign has now been associated with seven other conditions, including some cases of Senior–Løken syndrome, COACH syndrome, Dekaban–Arima syndrome, orofaciocigital syndrome type VI (Varadi–Papp) syndrome, and Malta syndrome, all of which have variable levels of ocular and renal involvement.

Renal disease in Joubert syndrome and Joubert-related disorders may present as cystic dysplasia or nephronophthisis, with corticomedullary cysts and tubulointerstitial nephritis. Ultrasound shows increased renal echogenicity in normal-sized kidneys with poor corticomedullary differentiation. Affected infants may be

asymptomatic at birth but develop urinary concentrating defects, polyuria, and progressive renal dysfunction during childhood. ESRD is common in the teenage years. Rarely, patients will present with a clinical picture similar to ARPKD; this is more common in patients with COACH syndrome and *MKS3* mutations.

Orofaciodigital Syndrome

Orofaciodigital (OFD) syndrome is a heterogeneous ciliopathy of 14 subtypes that are grouped together by the common finding of malformations of the face, oral cavity, and digits. OFD1 is an X-linked dominant condition that is lethal in males; the other 13 OFD subtypes are autosomal recessive and linked to a variety of cilia-associated genes. Tooth and tongue abnormalities, a buccal frenulum, agenesis of the corpus colosseum, and brachydactyly are common findings. Cleft lip and/or cleft palate occur in approximately one-third of patients. Renal cysts have been reported in 6% of children with orofacioidigital syndrome and in up to 70% of adults, and patients develop progressive renal insufficiency that results in ESRD in early adulthood (Saal et al., 2010).

Cranioectodermal Dysplasia

Cranioectodermal dysplasia, also called Sensenbrenner syndrome, is an autosomal recessive or sporadic ciliopathy associated with mutations in *IFT122*, *WDR35*, *IFT43*, and *WDR19*, all of which encode proteins that localize to the cilia; *IFT43* and *WDR35* are involved in axonal transport within the primary cilia. Patients have frontal bossing, dolichocephaly, low-set ears, wide-spaced eyes with epicanthal folds, small and widely spaced teeth, sparse hair, abnormal nails, short stature, a narrow thorax, short humeri, and brachydactyly. The liver and eyes may also be affected. Over half of patients will develop nephronophthisis that progresses to ESRD.

Renal–Hepatic–Pancreatic Dysplasia

Renal–hepatic–pancreatic dysplasia (RHPD), also called Ivemark syndrome, is an autosomal recessive disorder associated with mutations in *NPHP3*, which encodes nephrocystin 3, a protein that localizes to primary cilia (Fiskerstrand et al., 2010). Patients often present in utero with oligohydramnios caused by renal dysplasia with peripheral cortical cysts. Hepatic and pancreatic fibrosis is also present. Most patients develop the oligohydramnios sequence and die of respiratory failure soon after birth.

Glomerulocystic Kidney Disease

Glomerulocystic kidney disease is defined as dilation of the Bowman capsule around the glomeruli with or without tubular dilatation and renal cysts (Fig. 87.5). It is an autosomal dominant disorder associated with mutations in *UMOD* or *HNF1β* but may also be seen in ciliopathies, renal dysplasia, or associated with severe fetal renal damage. *HNF1β* encodes a transcription factor critical to embryologic development of the kidney, pancreas, liver, and Müllerian duct. Mutations in *HNF1β* are also associated with maturity-onset diabetes of the young, as in the “renal cysts and diabetes syndrome.” *UMOD* encodes uromodulin, which is linked to urinary tract renal defense but probably has other, currently unknown, functions in the kidney. Glomerulocystic kidney disease often presents in young children with renal hyperechogenicity on ultrasound, but presentation may be delayed into adulthood. Patients may be hyperuricemic. The kidneys generally progress to ESRD,

• **Fig. 87.5** Glomerulocystic Kidney Disease. Arrows show glomeruli inside dilated Bowman capsule; arrowheads indicate normal tubules. (Courtesy of Dr. Laura Finn, Seattle Children's Hospital, Department of Pathology, Seattle, Washington.)

but the rate of progression is highly variable (Bissler et al., 2010; Lennerz et al., 2010; Iorembere and Vehaskari, 2014).

Renal Tubular Dysgenesis

Renal tubular dysgenesis is an autosomal recessive disorder associated with mutations in genes for the renin–angiotensin system (*AGT*, *REN*, *ACE*, and *AGTR1*) that result in failure of renal proximal tubule development. Similar pathology may develop if renal blood flow is interrupted in utero, such as in a major cardiac anomaly, renal artery stenosis, twin–twin transfusion syndrome, or use of angiotensin-converting enzyme inhibitors or angiotensin receptor blockers during the second or third trimesters.

Patients present with severe oligohydramnios by 20–22 weeks' gestation, leading to the oligohydramnios sequence. The kidneys may appear normal on ultrasound, or there may be hyperechogenicity or decreased corticomedullary differentiation. The skull may have large fontanelles and sutures. Diagnosis is confirmed by renal biopsy showing the absence or dramatic reduction in the number of differentiated proximal tubules.

Most patients die in utero or in the neonatal period because of pulmonary hypoplasia and hypotension that is not responsive to standard medical therapy. In cases of refractory hypotension, fludrocortisone may improve the blood pressure; fresh frozen plasma may also be helpful in patients with an angiotensinogen mutation. Of the 150 patients reported with renal tubular dysgenesis, there are at least 10 reported cases of survivors past 18 months of age, 4 of whom have ESRD and 5 of whom have chronic kidney disease (Gubler, 2014).

Renal Teratogens

A number of commonly used medications have been associated with abnormal renal development. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers inhibit nephrogenesis when taken in the second and third trimesters, and they have been associated with renal tubular dysgenesis, ureteropelvic junction obstruction, and renal agenesis. Nonsteroidal antiinflammatory drugs, especially indomethacin, are linked to fetal and neonatal renal failure, probably because of their effects on the ductus

arteriosus. Mycophenolate mofetil is associated with a variety of organ anomalies, including renal anomalies. Tacrolimus may cause a mild and transient decline in renal function, but the placenta prevents an estimated 60% of the dose from reaching the fetus (Morgan et al., 2014). The breast cancer drug trastuzumab has been associated with oligohydramnios when used in the second or third trimester and is an Federal Drug Administration pregnancy category D medication. Gentamicin has been associated with nephrotoxicity in animal studies and two human cases of cystic dysplasia; however, these findings were not confirmed by a large Swedish study (Morgan et al., 2014). Maternal diabetes is associated with renal and urinary tract abnormalities, especially if it is present in the first trimester (Dart et al., 2015).

Inborn Errors of Metabolism

Multiple Acyl-CoA Dehydrogenase Deficiency

Multiple acyl-CoA dehydrogenase deficiency (MADD), also called glutaric acidemia type II or glutaric aciduria type II, is an autosomal recessive defect in the mitochondrial electron transfer chain caused by mutations in *ETFDH*, *ETFA*, or *ETFB*. This causes degeneration of cells that use fatty acids as a primary source of energy, including renal tubular epithelial cells. Affected children present in the neonatal period with lethargy, vomiting, a “sweaty feet” odor, nonketotic hypoglycemia, metabolic acidosis, and organic aciduria. Some will have other congenital anomalies, including a high forehead, low-set ears, wide-spaced eyes, a small midface, renal dysplasia, and renal cysts. Most patients who present near birth die within weeks to months despite attempts at dietary interventions. There is a milder, late-onset form of the disease, not associated with renal anomalies, which may be treated with riboflavin.

Smith–Lemli–Opitz Syndrome

Smith–Lemli–Opitz syndrome is an autosomal recessive disorder of cholesterol synthesis associated with mutations in *DHCR7*. The clinical spectrum is broad, ranging from asymptomatic cases to perinatal lethality. Affected children may have delayed growth, microcephaly with bitemporal narrowing, ptosis, a short nose with anteverted nares, micrognathia, epicanthal folds, and low-set ears. Mental retardation, cleft palate, heart defects, genital anomalies, and syndactyly of the second and third toes are common. One-fourth of patients have renal anomalies, including renal hypoplasia or agenesis, renal cortical cysts, or urinary tract anomalies.

Zellweger Syndrome

Zellweger syndrome, also called cerebrohepatorenal syndrome, is an autosomal recessive condition associated with mutation in any of 12 pexin genes, usually *PEX1*, leading to peroxisome dysfunction. Affected infants have severe hypotonia, absent reflexes, a high forehead and large anterior fontanelle, small supraorbital ridges, a triangular mouth, and low-set ears with abnormal lobes. There are usually small renal cysts and calcific stippling of the epiphyses. Severe liver dysfunction typically appears after 3 months of age. Some patients present with seizures caused by abnormal neuronal

migration. Death before age 1 year is common, though some patients survive longer with varying developmental outcomes (Baumgartner and Saudubray, 2002; Poll-The et al., 2004).

Congenital Disorders of Glycosylation

The congenital disorders of glycosylation (CDG) are a family of autosomal recessive defects in the synthesis of the glycans of glycoproteins (Hertz-Pannier et al., 2006). Patients can present with a variety of symptoms, including developmental delay, seizures, hypotonia, liver disease, protein-losing enteropathy, and dysmorphic facial features. Patients may have enlarged hyperechoic kidneys on ultrasound and renal tubular microcysts. Congenital nephrotic syndrome, associated with diffuse mesangial sclerosis pathology, has also been reported (Sinha et al., 2009).

Acknowledgments

Thank you to Dr. Laura Finn, Seattle Children’s Hospital Department of Pathology, for providing renal pathology images. Thank you to Jennifer McBroom, Seattle Children’s Hospital Department of Radiology, for providing ultrasound images.

Developmental Abnormalities of the Genitourinary System

PAUL A. MERGUERIAN AND COURTNEY K. ROWE

KEY POINTS

- Current American Urological Association guidelines do not recommend ultrasound for the evaluation of undescended testicles.
- Children with an undescended testicle should be referred to a pediatric urologist at approximately 6 months of age.
- Infants with bilateral nonpalpable testicles should be evaluated for possible congenital adrenal hyperplasia.
- Infants with hypospadias and unilateral or bilateral undescended testicles should be evaluated for disorder of sexual development.
- Repair of hypospadias is recommended at between 6 months and 1 year of age.
- Bladder exstrophy repairs are currently delayed to 3 months of age.
- A voiding cystourethrogram should be performed in infants with high-grade hydronephrosis and bilateral hydronephrosis.
- Most hydroceles in infants are noncommunicating, and infants should be referred to a urologist if they fluctuate in size suggesting a communicating hydrocele.
- Vesicoureteral reflux is more common in male infants and has a high rate of resolution.

Congenital anomalies of the kidney and urinary tract (CAKUTs) are found in around 0.5% of pregnancies and account for 20%–30% of all prenatally diagnosed congenital anomalies. In spite of prenatal diagnosis and aggressive treatment, they remain one of the main causes of renal failure in children. They are responsible for 30%–50% of all children with chronic renal failure worldwide (Pope et al., 1999).

Prenatal ultrasonography has dramatically changed the management of these conditions. Close to 90% of these conditions are detected prenatally. Most of these are asymptomatic and can be managed conservatively. It is imperative for pediatric providers caring for these patients to identify patients at risk of developing renal impairment.

The phenotypic spectrum of these disorders is shown in [Box 88.1](#). Ureteropelvic junction obstruction (UPJO) and vesicoureteral reflux (VUR) are the most common CAKUTs. Other forms of CAKUTs include multicystic dysplastic kidneys (MCDK), primary megaureter, duplicated collecting systems, ureterocele, renal

dysplasia, and bladder outlet obstruction such as posterior urethral valves (PUVs) (Ichikawa et al., 2002).

There are well-recognized features related to these anomalies in infants, and they include higher incidence of UPJ obstruction and VUR in males; UPJO and MCDK are often unilateral; most of these anomalies are associated with VUR; most infants with high-grade reflux have renal dysplasia; and primary megaureter is overwhelmingly found in males.

On the other hand, in older children there is a female preponderance of several of these CAKUTs.

It is postulated that these anomalies are based on defects in the same molecular pathways involved in kidney development. According to the Genitourinary Molecular Anatomy Project, there may be several hundred genes involved in the process of kidney development (Renkena et al., 2011; Schedl et al., 2007; Song and Yosypic, 2011).

Before we discuss the evaluation and management of these anomalies, it is important to discuss embryogenesis.

Early Kidney and Urinary Tract Embryologic Development

The development of the kidney and urinary tract begins when the nephric duct (ND) is formed from the intermediate mesoderm ([Fig. 88.1](#)). The ND extends caudally and induces the adjacent mesoderm to form two transient kidneys, the pronephros and the mesonephros (Mitchell and Sharma, 2009).

The pronephros contains rudimentary tubules that open into the pronephric duct and disappears at the end of the fourth week of gestation (Mitchell and Sharma, 2009).

The mesonephros then begins to develop and contains well-developed nephrons with vascularized glomeruli connected to proximal and distal tubules draining into the mesonephric duct. The mesonephric duct then fuses with the cloaca and contributes to the formation of the bladder trigone. In the male it also forms part of the genital system, including the vas deferens, seminal vesicles, epididymis, ejaculatory ducts, and the efferent ductules of the testis. In females the mesonephros forms vestigial structures, the epoophoron and the paroophoron (Renkena et al., 2011; Duke University School of Medicine, 2015).

The metanephros is the final stage of renal development and is identified at around 5–6 weeks' gestation. This structure consists of two components: the ureteric bud and the metanephric mesenchyme. The ureteric bud forms from the nearby caudal mesonephric (wolffian) duct and grows to penetrate the metanephric blastema. The reciprocal interaction between the ureteric bud and the metanephric mesenchyme results in branching of the ureteric bud to form the collecting system of the kidney. A mesenchymal-to-epithelial transition of the metanephric mesenchyme at each of the newly formed ureteric bud tips results in the development of the nephrons. With each division of the ureteric bud, a new layer of nephrons is induced from stem cells in the periphery of the organ. As development proceeds, the metanephros is located at progressively higher levels, reaching the lumbar position by 8 weeks' gestation (Duke University School of Medicine, 2015).

• BOX 88.1 Spectrum of Congenital Anomalies of the Kidney and Urinary Tract (CAKUT)

Renal agenesis
Renal dysplasia
Renal hypoplasia
Duplex kidney and ureter
Horseshoe kidney and other fusion anomalies (crossed fused ectopia)
Ureteropelvic junction obstruction
Megaureter (obstructing, refluxing, nonobstructing, nonrefluxing)
Ectopic ureter
Ureterocele

It has also been found that the main ureteric duct (future ureter) undergoes a process of temporary obliteration followed by recanalization of the lumen as the embryo grows. This process begins in the middle zone of the ureter and progresses proximally and distally. In embryos of approximately 17 mm in length the primary ureter forms a solid cord, and in a 23-mm embryo it is totally patent. These observations have given rise to the theory that UPJO and ureterovesical junction obstruction arise from incomplete recanalization of the ureter at its most proximal and distal ends (Baker and Gomez, 1998; Duke University School of Medicine, 2015).

The ureteral orifice is also transposed from its original budding site on the wolffian duct into the bladder. This transposition occurs with expansion of the terminal part of the duct and its incorporation into the base of the bladder as the hemitrigone. If, for example, the bud arises caudally on the duct, the orifice becomes incorporated onto a long cornu of the hemitrigone and is therefore laterally displaced. This lateral displacement causes the submucosal tunnel to be short, leading to VUR (Baker and Gomez, 1998).

All the branches of the ureteric bud and the nephrons have been formed by 32–36 weeks' gestation. However, these structures will continue to mature after birth. Once matured, humans have an estimated 300,000 to 1 million nephrons per kidney (Bertram et al., 2011).

Anomalies of the Kidney

Renal Agenesis

Renal agenesis is the congenital absence of the kidneys and can be bilateral or unilateral. Bilateral renal agenesis occurs in roughly

• Fig. 88.1 Development of the human kidney.

1 in 4000 births, with male predominance (Potter, 1965). Prenatally it is discovered in the second or third trimester because of severe oligohydramnios on ultrasound. Findings of absent kidneys, no bladder filling, and lack of renal arteries on color Doppler ultrasonography support the diagnosis (Dias et al., 2014). Postnatally, infants are noted to have the characteristic Potter facies with a prominent skin fold from the eye to the cheek, blunted nose, low-set ears, and orthopedic abnormalities, including clubbed legs or fused lower extremities. Lack of adequate amniotic fluid results in pulmonary hypoplasia and respiratory distress (Peters et al., 1991). These findings or lack of urine output within 24 hours should prompt renal ultrasound. Bilateral renal agenesis is almost universally fatal, with 40% demise in utero, and those born alive surviving for less than 48 hours because of pulmonary compromise, although there have been reports of survival of monoamniotic twins discordant for bilateral renal agenesis (Perez-Brayfield et al., 2004) and a report of bilateral renal agenesis managed with serial amnioinfusion with survival of the infant to 9 months (Bienstock et al., 2014). There is an increased prevalence of congenital renal anomalies in relatives, and screening ultrasound has been recommended for parents and siblings (Roodhooft et al., 1984; Schwaderer et al., 2007).

Unilateral renal agenesis occurs in roughly 1 in 500 to 1 in 1000 births. The true incidence can be difficult to measure because of the frequent involution of multicystic dysplastic kidneys. In fetal ultrasounds with a unilateral empty renal fossa, 47% have an absent kidney at birth, while most of the rest have renal ectopia (Chow et al., 2005). Unilateral renal agenesis is associated with abnormalities of the paramesonephric and mesonephric ducts, including absence of the ipsilateral uterine horn or vas deferens. It is also associated with a number of multisystem syndromes, including DiGeorge syndrome, Kallmann syndrome, Klinefelter syndrome, Mayer-Rokitansky-Küster-Hauser syndrome, Townes-Brocks syndrome, and Williams-Beuren syndrome (Woolf and Hillman, 2007). There is an increased risk of contralateral renal anomaly, including VUR in a third of patients; infants with unilateral renal agenesis should undergo a screening VCUG (Kaneyama et al., 2004).

Despite reassuring studies indicating that patients with solitary kidneys after donor nephrectomy have a low risk of developing end-stage renal disease (Reese et al., 2015), new evidence shows increased risk of renal failure in patients with a congenital cause of their solitary kidney, with 50% requiring dialysis by 30 years of age (Sanna-Cherchi et al., 2009). The American Academy of Pediatrics does not recommend sports restrictions because of the low risk of renal injury (Grinsell et al., 2012), but children with unilateral renal agenesis should be followed up regularly to monitor blood pressure, for urinalysis, and to monitor glomerular filtration rate (Westland et al., 2013).

Renal Ectopia and Fusion

Renal ectopia describes a kidney that fails to reach its standard location; instead it can be pelvic, iliac, abdominal, thoracic, and contralateral or crossed. This occurs in about 1 in 700 on ultrasound screenings (Caiulo et al., 2012). Abnormalities of renal ascent during fetal development are thought to be the cause of ectopia. Most patients are asymptomatic.

Half of ectopic kidneys are hydronephrotic, of which 50% are due to obstruction, 25% are due to vesicoureteral reflux, and 25% are due to abnormal rotation without obstruction (Gleason et al., 1994). There is a strong association with genital anomalies, which

are seen in almost half of patients (Rivard et al., 1978). This is pronounced in females, and a large number of girls with müllerian anomalies, including cloacal anomalies, are also noted to have ectopic kidneys (Leduc et al., 1968; Warne et al., 2002). Because of this, the finding of an ectopic kidney in a female should prompt further investigation. Prognosis for the ectopic kidney is good, with no evidence of adverse effects on blood pressure or renal function (van den Bosch et al., 2010).

When the ectopic kidney is located on the opposite side from where its ureter enters the bladder, this is called *crossed renal ectopia*. This is found in about 1 in 1000 on autopsy, and 90% of these kidneys are also fused to the adjacent kidney (Abeshouse and Bhisitkul, 1959). The cause is unknown. This condition is found more commonly in males, and left-to-right crossover is most frequent (Gu and Alton, 1991; Bhatt and Herts, 2014). About 20% of patients with crossed renal ectopia also have VUR (Guarino et al., 2004), and there is a high incidence of associated skeletal and genital anomalies with solitary crossed renal ectopia, although it is not known if this is due to the ectopia or the agenesis (Gu and Alton, 1991; Gleason et al., 1994).

The most common fusion abnormality is the horseshoe kidney, which consists of two renal masses on either side of the midline connected by an isthmus of tissue. It is found in approximately 1 in 600 on radiographic review (Weizer et al., 2003). There is an increase in associated genitourinary anomalies, including hypospadias, undescended testes, bicornuate uterus, septate vagina, and duplication of the ureter (Boatman et al., 1972). Up to half of children with horseshoe kidney have associated VUR (Taghavi et al., 2016).

Most patients with horseshoe kidney are asymptomatic, although the incidence of Wilms tumor is higher in patients with horseshoe kidney than in the average population (Huang et al., 2004), and there is a high prevalence of stones in adulthood (Taghavi et al., 2016). Neither risk is significant enough to justify routine screening of these patients.

Supernumerary Kidney

A supernumerary kidney is a separate or loosely attached renal mass with its own blood supply and collecting system. It is exceedingly rare, with only about 100 cases reported (Sureka et al., 2014). This condition is usually diagnosed when the supernumerary kidney becomes infected or obstructed, as about 50% have a structural abnormality such as a duplicated system or hydronephrosis (N'Guessan and Stephens, 1983).

Cystic Disease of the Kidney

Cystic diseases of the kidney are classified as having inheritable or noninheritable causes (Box 88.2). Many will present during the neonatal period.

Autosomal recessive polycystic kidney disease presents as symmetric enlargement of the kidneys bilaterally due to collecting duct cysts and is associated with biliary dysgenesis and portal fibrosis. This disease used to be referred to as *infantile*; however, mild cases can present later in life. The incidence is estimated at 1 in 20,000 live births, with a mutation of *PKHD1* located on chromosome 6 responsible for this disease (Zerres et al., 1994). Ultrasound findings of bilateral hyperechoic kidneys with poor corticomedullary differentiation are suggestive, and infants often have Potter facies and respiratory issues due to oligohydramnios. Thirty percent to 40% of patients die shortly after birth of

• BOX 88.2 Cystic Diseases of the Kidney

Inheritable

- Autosomal recessive (infantile) polycystic kidney disease
- Autosomal dominant (adult) polycystic kidney disease
 - Juvenile nephronophthisis and medullary cystic disease complex
 - Juvenile nephronophthisis (autosomal recessive)
- Medullary cystic disease (autosomal dominant)
- Congenital nephrosis (familial nephrotic syndrome) (autosomal recessive)
- Familial hypoplastic glomerulocystic disease (autosomal dominant)
- Multiple malformation syndromes with renal cysts (e.g., tuberous sclerosis, von Hippel–Lindau disease)

Noninheritable

- Multicystic kidney (multicystic dysplastic kidney)
- Benign multilocular cyst (cystic nephroma)
- Simple cysts
- Medullary sponge kidney
- Sporadic glomerulocystic kidney disease
- Acquired renal cystic disease
- Calyceal diverticulum (pyelogenic cyst)

Modified from the American Academy of Pediatrics, Section on Urology (Glassberg et al., 1987).

• **Fig. 88.2** Sonographic view of a multicystic dysplastic kidney in which multiple cysts that do not communicate with one another are grouped together, giving the typical “bunch of grapes” appearance. No function was noted on the patient’s renal scan, confirming this diagnosis.

pulmonary complications or sepsis (Guay-Woodford et al., 2014). Those who survive have a high risk of developing childhood renal insufficiency, systemic hypertension, and portal hypertension, with many requiring renal or liver transplants (Guay-Woodford and Desmond, 2003).

Autosomal dominant polycystic kidney disease involves progressive cystic enlargement of bilateral kidneys due to a mutation in at least three different genes (*PKD1*, *PKD2*, and *PKD3*) that leads to an abnormal form of the protein polycystin (Grantham, 1996). It is the most commonly inherited renal disease, occurring in 1 in 500 to 1 in 1000 live births. While it used to be diagnosed late in life, advances in radiographic imaging have allowed early detection in fetuses and infants (Boyer et al., 2007). Renal failure is variable and is usually preceded by hypertension and hematuria between 30 and 50 years of age (Johnson and Gabow, 1997). The condition is associated with intracranial aneurysms, abdominal wall hernias, and cysts in the liver, seminal vesicles, and other areas (Luciano and Dahl, 2014). Screening of asymptomatic family members is recommended for adults but not children (Chapman et al., 2015).

Tuberous sclerosis complex is a neurocutaneous disease that presents with benign hypopigmented skin lesions and is associated with epilepsy or autism. Renal manifestations can mimic other cystic diseases, and long-term urologic sequelae include renal angiomyolipomas, which can be treated with surgery or the mammalian target of rapamycin complex 1 (mTORC1) inhibitor everolimus (DiMario et al., 2015).

Multicystic dysplastic kidney disease is the most common type of renal cystic disease (Fig. 88.2), occurring in 1 in 4000 live births, with increasing incidence (Schreuder et al., 2009). It is diagnosed on the basis of ultrasound findings of a collection of cysts of various sizes without any evidence of renal parenchyma. There is a male and a left-sided predominance. The cause is unknown. Since half of MCDK will involute spontaneously by age 10 years, nephrectomy is generally reserved for symptoms such as urinary tract infection or hypertension (Eickmeyer et al., 2014). One-third of patients will have an anomaly in the contralateral

kidney, and most of these will have vesicoureteral reflux; a screening voiding cystourethrogram (VCUG) can be considered (Schreuder et al., 2009). Less than 10% of patients will go on to develop hypertension, while up to 17% will develop proteinuria and chronic kidney disease; both appear to be most common in patients with contralateral renal anomalies (Mansoor et al., 2011).

Renal Tumors

Malignancies are rare in neonates, and renal tumors make up only approximately 7% of neonatal tumors (Powis, 2010). About 15% are discovered on prenatal ultrasound, with half noted on physical examination as a palpable abdominal or flank mass (Isaacs, 2008). The first line of treatment is radical nephrectomy for all unilateral renal tumors. Biopsy before surgery is generally reserved for complex cases such as those with bilateral disease or metastases at presentation.

The most common renal tumor in neonates is congenital mesoblastic nephroma, generally diagnosed before 3 months of age. There is a male predominance of 1.5:1. The mainstay of treatment is a radical nephrectomy, and surgery is generally curative in stage I/II tumors, with rare need for chemotherapy. The overall survival rate is excellent, around 95% (Gooskens et al., 2017).

Wilms tumor is the second most common neonatal renal tumor and affects males and females equally. Treatment generally begins with radical nephrectomy, although partial nephrectomy for bilateral tumors or patients with a syndrome that predisposes them to reoccurrence is becoming more common (Wilcox Vanden Berg et al., 2016). After surgery, treatment is based on risk stratification and may include chemotherapy and radiation therapy based on protocols from two international oncologic groups, the Children’s Oncology Group and the International Society of Paediatric Oncology (Dome et al., 2015). The overall survival rate is high at 90%, but 60% of long-term survivors report chronic health problems, with 25% of those experiencing severe issues, including congestive heart failure, hypertension, and renal failure (Termuhlen et al., 2011).

Malignant rhabdoid tumor of the kidney is a rare and aggressive cancer that generally presents at advanced stages. The overall survival rate in neonates is less than 10%. Other renal tumors in neonates include clear cell carcinoma of the kidney, which presents at advanced stage but for which there is an overall survival rate of 50%, ossifying renal tumor of infancy, which is generally benign, nephroblastomatosis, which is a premalignant condition requiring observation, and cystic nephroma, which is benign but indistinguishable from rare malignancies and therefore generally surgically removed (Powis, 2010).

Renal Vein Thrombosis

The risk factors for renal vein thrombosis include perinatal asphyxia, maternal diabetes, and dehydration as well as the presence of prothrombotic factors such as protein C and protein S deficiency and factor V Leiden (Lai et al., 2012). The classic presentation is gross hematuria, a palpable flank mass, and thrombocytopenia. Contrast angiography is the gold standard for diagnosis, but because of concerns regarding radiation, Doppler ultrasound is often used as an alternative. This will show enlarged and echogenic kidneys with either absent flow in the renal vein or increased resistance in the renal artery (Resontoc and Yap, 2016). The mainstay of treatment is supportive care, but heparin and low-molecular-weight heparin are being used more often for bilateral disease or inferior vena cava involvement. Regardless of the treatment chosen, about 70% of the affected kidneys will become atrophic (Lau et al., 2007; Marks et al., 2005).

Adrenal Hemorrhage

Adrenal hemorrhage occurs after birth in approximately 2 in 1000 live births and presents with anemia, hyperbilirubinemia, or scrotal hematoma (Lai et al., 2012). While palpable abdominal masses have been reported, this is a less common finding in the era of ultrasound diagnosis. Predisposing factors include vaginal birth, macrosomia, perinatal hypoxia, and sepsis (Gyurkovits et al., 2015). Treatment is generally supportive, with spontaneous resolution on subsequent imaging (Postek et al., 2011).

Anomalies of the Ureters

Duplication of the Ureters

Ureteral duplication can develop if there are duplicate ureteral buds or early division of these buds. It occurs in between 0.8% and 1.8% of the population (Privett et al., 1976; Wein et al., 2016). Ureteral triplication and even quadruple ureters have also been reported in the literature but are much rarer. Complete duplication results in two separate ureters, while partial duplication results in a bifid renal pelvis with distal confluence into a single ureter. There is a strong genetic link to duplication of the ureter, which occurs in 12% of screened siblings and parents of affected patients (Carter, 1984). Diagnosis is generally by ultrasound, and some clues can indicate a duplex kidney prenatally, including renal length greater than the 95th percentile with a cyst-like structure in the upper pole surrounded by a rim of parenchyma, two noncommunicating renal pelvises, or a cystic structure in the bladder consistent with a ureterocele (Dias et al., 2014). The location of the ureters in the bladder of patients with complete ureteral duplication generally follows the Weigert–Meyer law, with the upper pole ureter found caudal to the lower pole ureter.

About half of patients with duplex kidneys are otherwise asymptomatic, and the anomaly by itself is not thought to have any clinical significance. It is, however, associated with other conditions; a quarter of patients have upper pole obstruction, usually associated with a ureterocele, 10% have lower pole scarring, and 4% have lower pole VUR (Doery et al., 2015). Both lower pole UPJO and rarely upper pole UPJO have been reported, as has upper pole ectopia. Long-term renal outcome is generally related to the presence of these associated conditions, although ureteral duplication itself is a risk factor for a slower rate of spontaneous reflux resolution (Estrada et al., 2009).

Ureteral Ectopia

Ureteral ectopia occurs whenever the opening of the ureter is in a position other than the expected location in the bladder trigone. The incidence is 1 in 1900 on autopsy study (Mathiot et al., 2004). The cause is thought to be from ectopic location of the initial ureteric bud, and because of the predictable pathway of the bud during embryologic development, these ureters are generally found in predictable locations. The most common form is lateral migration, which is thought to cause vesicoureteral reflux. Medially located ureters are generally found along the path of the wolffian duct. In males an ectopic ureter can be found in the bladder neck, the posterior urethra, seminal vesicles, the vas deferens, or the epididymis. In females an ectopic ureter can be found in the bladder neck, the urethra, the uterus, the proximal part of the vagina, or the Gartner duct (Wein et al., 2016).

In males the ectopic ureter can present with dilatation or infection of the structure into which it inserts (El-Ghar and El-Diasty, 2013). In females the ectopic position is more likely to be distal to the urethral sphincter, resulting in continuous incontinence, which is often discovered after failed attempts at toileting train. Ectopic ureters are generally from the upper pole of a duplex kidney. While single-system ureteral ectopia occurs, it is difficult to diagnose because of the association with poor renal function on that side but should be considered in females who present with continuous urinary incontinence and what appears to be a solitary kidney on conventional imaging (Borer et al., 1998). Dimercapto-succinic acid scanning and computed tomography are the most sensitive techniques for diagnosis, although ultrasound, MRI, and intravenous pyelogram can also detect a single-system ectopic ureter (Lee et al., 2016).

Ureterocele

A ureterocele is a cystic dilatation of the distal submucosal or intravesical ureter that results in obstruction of urine flow. It can occur within a single system or a duplex system; if the system is duplex, the ureterocele is associated with the ectopic upper pole. Ureteroceles occur in between 1 in 500 and 1 in 4000 in autopsy series (Sözübir et al., 2005). The cause is thought to be failure of apoptosis of a distal membrane at the ureteral orifice known as the *Chwalle membrane*. Because of familial occurrence, this is thought to have a genetic cause (Mendelsohn, 2009). Ultrasound of ureteroceles shows hydronephrosis associated with a cystic structure within the bladder (Fig. 88.3). Most are now diagnosed prenatally and have been detected as early as 16 weeks (Godinho et al., 2013). Prenatal symptoms include infection, retention, or prolapse through the urethra in a female, which generally presents as a bulging vulvar mass (Abdelgadir et al., 2010).

• **Fig. 88.3** Images demonstrating upper pole hydronephrosis that is secondary to a dilated ureter (A), which empties into a larger ureterocele within the bladder (evident in [B]). There is also secondary dilatation of the lower pole renal pelvis. The ureterocele is demonstrated as the cystic filling defect on bladder views from the ultrasound study (B) as well as the voiding cystourethrogram (C).

Multiple options have been described for management. Ureteroceles can be managed with observation if the child has no infections and minimal associated vesicoureteral reflux, and a diuretic renogram shows no obstruction or an already nonfunctioning portion of the kidney. Appropriately selected patients have needed no further intervention (Pohl, 2011). For patients who require treatment, transurethral incision or puncture provides decompression in a minimally invasive fashion, although it can result in secondary vesicoureteral reflux. It is most successful as a definitive operation in patients with intravesical single-system ureteroceles and can also be used as an urgent temporizing measure in septic, obstructed children (Byun and Merguerian, 2006). Fetoscopic incision and puncture have also been described (Godinho et al., 2013). More definitive surgical procedures include ureteroureterostomy, ureteropyelostomy, and ureterocele excision with reimplantation into the bladder for functioning renal units or nephrectomy or heminephrectomy for nonfunctioning renal units. Regardless of the management selected, most children do well in the long term, with low risk of major bladder dysfunction (Paye-Jaouen et al., 2015).

Ureteropelvic Junction Obstruction

Ureteropelvic junction obstruction refers to a blockage where the renal pelvis meets the ureter. It occurs in an estimated 1 in 1500 live births and is the most common cause of prenatal hydronephrosis (Fig. 88.4), accounting for 41% of cases (Brown et al., 1987; Morin et al., 1996). UPJO in newborns and infants is generally caused by intrinsic narrowing of the area, while in childhood and adolescence it is generally caused by extrinsic compression by an accessory vessel to the lower pole of the kidney. Because of increased prenatal ultrasound screening, many cases are diagnosed prenatally, although delayed presentations can occur with flank pain, nausea, and emesis later in life. Diagnosis of functional obstruction is confirmed with a diuretic renogram.

Up to half of patients will require intervention because of worsening hydronephrosis or decreasing renal function (Chertin et al., 2006). Surgery is still primarily performed in an open fashion, but laparoscopic or robotic surgery is equally successful (Liu et al., 2014). While surgical success rates are between 90% and 100%, patients are still at risk of later development of hypertension and

• **Fig. 88.4** An example of prenatal hydronephrosis consistent with a partial ureteropelvic junction obstruction (A) that spontaneously resolved over a 6-month period (B).

proteinuria (Lee et al., 2014). Half of patients with UPJO will have other urologic anomalies, including contralateral obstruction and VUR (Lebowitz and Blickman, 1983; Karnak et al., 2008). A routine VCUG is generally recommended if UPJO is present, although some pediatric urologists are questioning the benefit of this invasive test because of the high prevalence of clinically insignificant reflux (ElSheemy et al., 2017; Weitz and Schmidt, 2017).

Uterovesical Obstruction

Uterovesical obstruction, also sometimes called an *obstructed megaureter*, refers to a blockage where the ureter meets the bladder. The cause is thought to be an adynamic segment of the distal ureter with insufficient peristalsis (Wein et al., 2016). Megaureter accounts for 5%–10% of prenatal hydronephrosis, and up to 80% of cases resolve without the need for intervention (Nguyen et al., 2010; Di Renzo et al., 2013). The true incidence of obstructed megaureter is not known. As with UPJO, uterovesical obstruction is confirmed with the functional study of a diuretic renogram since not all megaureters are obstructed. Surgical management can be with endoscopic treatment or open reconstruction (Farrugia et al., 2014).

Vesicoureteral Reflux

Vesicoureteral reflux describes retrograde flow of urine from the bladder to the ureters. The normal ureterovesical junction is designed with a long intramural tunnel through which the ureter travels before reaching the bladder that prevents retrograde flow of urine. Primary VUR is thought to be due to an abnormal or immature formation of this area, allowing urine to reflux from the bladder into the ureters and kidneys.

As many as 17% of all children may have VUR, including 30% of those who develop a urinary tract infection (Sargent, 2000). The first sign of VUR is often hydronephrosis on the prenatal ultrasound, with 20% of these infants eventually found to have reflux (Passerotti et al., 2011). Neonates with a history of unilateral prenatal hydronephrosis should undergo ultrasound again within the first week of life; if the hydronephrosis was bilateral or in a solitary kidney, this should be done before discharge from the hospital (Nguyen et al., 2010). Patients with high-grade

hydronephrosis on late prenatal or postnatal imaging should be screened with a VCUG (Peters et al., 2010).

VUR is graded after a VCUG from I to V. Lower-grade reflux is more likely to resolve spontaneously without the need for intervention, with spontaneous resolution seen in about 50% of patients with grade III reflux (Estrada et al., 2009). Continuous antibiotic prophylaxis is recommended for infants with grade III–V VUR or any grade if the infant has a history of febrile urinary tract infection. There is evidence that prophylaxis prevents recurrent infections, but its benefit in terms of renal scarring is less clear (RIVUR Trial Investigators, 2014). Another option for reducing the risk of urinary tract infection is circumcision (Morris and Wiswell, 2013). Breakthrough infections despite continuous administration of prophylactic antibiotics generally trigger a change in the antibiotic or surgical correction via an open or endoscopic approach.

About 27% of siblings and 36% of children of patients with VUR will have reflux. A screening ultrasound can be considered, with a VCUG pursued if there is evidence of renal scarring or a history of urinary tract infection (Skoog et al., 2010).

Anomalies of the Bladder

Bladder Exstrophy

Bladder exstrophy and epispadias are congenital anomalies that have characteristic external physical manifestations. The anterior portion of the bladder and/or urethra and abdominal wall structures are deficient, and the symphysis pubis is widely separated from the midline (Figs. 88.5–88.6).

This deformity has been described as “if one blade of a pair of scissors were passed through the urethra of a normal person; the other blade were used to cut through the skin, abdominal wall, anterior wall of the bladder and urethra, and the symphysis pubis; and the cut edges were then folded laterally as if the pages of a book were being opened” (Brock and O’Neill, 1998). This defect is usually found in isolation, with other organ systems, including the kidneys, rarely affected. Bladder exstrophy occurs at a rate of 1 per 10,000 to 1 per 50,000 live births. It occurs more commonly in males than females, with a ratio of 2.3:1 (Engel, 1974).

The defect may be diagnosed prenatally as ultrasonography can reliably detect exstrophy with the following findings: (1) an absent

• **Fig. 88.5** Male patient with bladder exstrophy showing exstrophied bladder, low umbilicus, and penile and urethral defect.

• **Fig. 88.6** Female patient with bladder exstrophy showing exstrophied bladder and bifid clitoris.

or nonfilling bladder, (2) a mass protruding from the abdominal wall, (3) normal kidneys with a low-set umbilicus, (4) an abnormal iliac crest widening, and (5) an anteriorly displaced scrotum (Mirk et al., 1986; Gearhart et al., 1995; Wilcox and Chitty, 2001). Prenatal diagnosis also allows better counseling of parents as the overall prognosis of these children is excellent if they are treated in specialized centers. Counseling of families by healthcare providers unfamiliar with the long-term outcomes has led to an increase in the abortion rate for these fetuses (Cacciari et al., 1999).

The pathogenesis of bladder exstrophy is thought to be caused by persistence of the cloacal membrane during development. This, in return, prevents the mesoderm from fusing in the midline. The persistent cloacal membrane then ruptures to produce an exstrophic condition (Muecke, 1964).

Management after delivery includes ligation of the umbilical cord with silk suture rather than plastic or metal clamp to prevent trauma to the exposed bladder. A hydrated gel dressing or even

plastic wrap placed on the exposed bladder protects it from superficial trauma. The dressing should be replaced daily and the bladder irrigated with saline with each diaper change. A renal ultrasound and a pelvic radiograph should be performed to evaluate the kidneys and the pubic diathesis. If a sacral dimple is found, a spinal ultrasound should be performed to rule out spinal cord tethering.

Surgical management has evolved, with most centers today performing a complete primary repair of exstrophy, which includes closure of the bladder exstrophy, reconstruction of the bladder neck, repair of the dorsal chordee, repair of epispadias with urethroplasty, and bilateral iliac osteotomies. Some still advocate a staged repair with closure of the bladder exstrophy and bladder neck as the first stage, repair of the epispadias as a second stage, and bladder neck reconstruction at around age 4–5 years (Grady and Mitchell, 1999; Inouye et al., 2013).

The timing of repair has also undergone some recent changes. In the past these repairs were primarily performed at birth. Recently many have advocated delayed closure at around 3 months of age, and this was based on studies showing that delayed closure does not compromise the rate of bladder growth (Baradaran et al., 2012; Ferrara et al., 2014; Borer et al., 2015). Delayed closure allows better coordination of care with the best team of urologists, orthopedic surgeons, anesthesiologists, and operating room staff present at the time of closure. Moreover, it allows the child to bond with the parents and allows penile growth to occur because of the physiologic surge of testosterone.

All children will develop VUR after surgery and should be given antibiotic prophylaxis for at least the first 18 months of life.

The goal of reconstruction includes preservation of renal function, urinary continence with volitional voiding, and functional and cosmetically acceptable external genitalia. With the primary repair, volitional voiding can be achieved with a single operation in around 40% of children, with around 40% requiring further bladder neck reconstruction at age 4–5 years to achieve continence. A small percentage of patients with small bladders will require reconstruction, including bladder augmentation and use of intermittent catheterization (Ellison et al., 2016).

Cloacal Exstrophy

Patients with cloacal exstrophy have multiple organ systems affected, and as a result it is also referred to the *OIES complex* (omphalocele, exstrophy, imperforate anus, and spinal defects). Other organ systems affected may include the extremities, the upper urinary tract, and the cardiovascular, pulmonary, and craniofacial systems. In this condition the hindgut is also open to the abdominal wall and separates the hemibladder plates.

Before the 1960s cloacal exstrophy was considered incurable, with a very high mortality rate. In the past 2 decades, survival rates have increased to close to 100% (Fullerton et al., 2016). The principles of management include neurologic evaluation for assessment of myelomeningocele, neonatal closure of omphalocele and intestinal diversion using the exstrophied hindgut, approximation of bladder halves, delayed bladder exstrophy closure with placement of the bladder deep in the pelvis, and iliac osteotomies (Shah et al., 2014).

Patent Urachus

The urachus is a tubular structure that connects the urogenital sinus and the allantois. It begins to narrow at between 4 and 5

months' gestation, generally being obliterated before birth. A patent urachus is often diagnosed because of drainage of clear fluid from the umbilicus. While ultrasound will often show the anomaly, a VCUG or sinogram can be used to confirm the diagnosis (Mesrobian et al., 1997). Because there is evidence that a patent urachus will be obliterated with time, surgery is generally avoided in patients younger than 1 year (Lipskar et al., 2010). If excision is required, it can be performed via the open or laparoscopic approach.

Posterior Urethral Valves

PUVs are a congenital obstruction of the posterior urethra. They are the most common cause of bladder outlet obstruction in newborn males, affecting approximately 2 in 10,000 live births, and occur only in males (Malin et al., 2012). They have been classified into three types since the 1920s. Type 1 valves account for the majority of PUVs, with leaflets of tissue arising from the verumontanum and fusing in the midline. Type 2 valves have not been described since the initial reports and likely do not exist. Type 3 valves are an annular ring thought to be due to persistence of the urogenital membrane (Young et al., 1919).

Prenatal ultrasound is often able to detect PUVs, with classic findings of a thickened, dilated bladder with bilateral hydroureter, especially in the presence of oligohydramnios and a dilated posterior urethra with the "keyhole sign" although some of these anomalies may be present in urethral atresia as well (Robyr et al., 2005). A VCUG is used to confirm the diagnosis after birth and will clearly show the obstructing membranes in the urethra (Fig. 88.7).

PUVs have consequences for multiple organ systems. Pulmonary hypoplasia and Potter facies can be seen if the obstruction was severe enough to cause oligohydramnios. Renal dysplasia is common

and can lead to progressive renal failure later in life, often associated with polyuria and nephrogenic diabetes insipidus. The bladder is generally small, with poor compliance that progresses to myogenic failure over time. The ureters often remain chronically dilated (Wein et al., 2016).

Initial management of PUVs involves support in the neonatal intensive care unit and passage of a urinary catheter for drainage. There is some evidence that inflation of a catheter balloon can cause ureteral obstruction in the valve bladder, and so this should be avoided (Jordan and Hoover, 1985). Once the infant is stable to undergo the procedure, the valves are ablated endoscopically. Vesicostomy is reserved for infants with urethras that are too small to accommodate the scope, while upper tract diversion is not felt to offer any significant benefit in terms of drainage or future renal function (Farhat et al., 2000).

Long-term renal outcomes are poor, with 20%–60% of boys progressing to end-stage renal disease. Nadir creatinine level is predictive of eventual renal outcome, with initial creatinine nadir level greater than 1.0 mg/dL generally used in modern series as the cutoff to predict a high risk of future renal damage (Sarhan et al., 2011; Bilgutay et al., 2016). The bladder decompensates to an overly large bladder with poor sensation and elevated postvoid residuals that often require overnight catheter drainage (Koff et al., 2002).

In the past decade a number of fetal interventions have been trialed for PUVs. These include vesicoamniotic shunting and fetoscopic valve ablation. While oligohydramnios abates and perinatal mortality is reduced, there is no evidence of a decrease in the percentage of patients who progress to end-stage renal disease (Farrugia, 2016).

Genital Abnormalities in Males

Cryptorchidism

Cryptorchidism, also known as *undescended testicle*, is one of the most common congenital anomalies. The incidence is variable and dependent on gestational age. The incidence ranges from 1% to 4.6% in full-term infants and from 1.1% to 45.3% in premature infants (Kolon et al., 2004). During the first 3–6 months of life the testicle may spontaneously descend such that the incidence at 1 year of age is around 0.7%–1%.

The main reasons for treating this condition are impaired fertility potential, testicular cancer, and testicular torsion. The number of spermatogonia per tubule is adversely affected in boys with undescended testicles beyond 1 year of age, and therefore it is recommended that orchiopexy be performed before 1 year of age to minimize germ cell loss (Hadziselimovic and Herzog, 2001).

This condition is commonly seen in healthy infants but can occur in conjunction with more than 400 syndromes (Visser, 1982). The cause is thought to be multifactorial and includes familial predisposition and environmental exposure (phthalates, pesticides, flame retardants). It has also been included in "testicular dysgenesis syndrome," a mechanism that interferes with normal fetal testicular development and includes undescended testicles and genitourinary disorders such as hypospadias, semen production abnormalities, and infertility (Barthold, 2008). A newborn "male" with bilateral nonpalpable gonads should be evaluated for possible disorder of sexual differentiation (DSD) such as congenital adrenal hyperplasia (CAH). Patients with a unilateral nonpalpable testicle and hypospadias should also be evaluated for a DSD; namely, mixed gonadal dysgenesis or ovotesticular DSD (Kolon et al., 2014).

• **Fig. 88.7** This voiding cystourethrogram shows a classic posterior urethral valve, with narrowing of the urethra at the most distal end of the prostate. This area corresponds to a flap of tissue that serves as an obstructing valve leaflet.

The most recent American Urological Association guidelines on the management of cryptorchidism state: “Providers should refer infants with a history of cryptorchidism (detected at birth) who do not have spontaneous testicular descent by six months (corrected for gestational age) to an appropriate surgical specialist for timely evaluation (Evidence Strength: Grade B).” The consensus on surgical management is that orchiopexy should be performed at around 6 months of age and before the age of 1 year. Surgically bringing the testicles into the scrotum may reduce but does not prevent the long-term sequelae such as infertility and cancer (Kolon et al., 2014).

Hypospadias and Chordee

This is one of the most common abnormalities of the penis and occurs in 1 in every 250–300 male births, or around 0.5% of all male births (Stoll et al., 1990; Schnack et al., 2008). From an analysis of all boys born in Denmark between 1973 and 2005, it was found that the relative recurrence risk for a brother to have hypospadias was 13.4 (95% confidence interval [CI] 11–16.4) and 10.4 (95% CI 7.54–14.4) for offspring of an affected male. The risk in same-sex twins was 50.8 (95% CI 34.2–75.5) (Schnack et al., 2008).

The term *hypospadias* means an abnormally located urethra. The defect is a spectrum that includes an abnormal ventral curvature (chordee) of varied degree, a dorsally hooded foreskin, and penoscrotal transposition. The spectrum ranges mild chordee without hypospadias to severe chordee and hypospadias with the meatus in a perineal location. A small group of patients will have a normally formed foreskin such that the hypospadias is discovered at the time of circumcision. These children also have a wide urethral plate and thus are described as having megameatus hypospadias (Centers for Disease Control and Prevention, 2017).

In most cases hypospadias is the only abnormal finding. In about 10% of children, hypospadias may be a part of a syndrome with multiple anomalies (Stoll et al., 1990; Schnack et al., 2008). The most common defect is cryptorchidism, reported in around 3% of infants with distal hypospadias and in up to 10% of infants with proximal hypospadias (Wu et al., 2002). In one study chromosomal anomalies were found in 22.2% of patients with hypospadias and cryptorchidism (Yamaguchi et al., 1991). DSD such as CAH and mixed gonadal dysgenesis should be considered when hypospadias is found with either a unilateral or bilateral undescended testicles (McAleer and Kaplan, 2001; Cox et al., 2008).

Hypospadias is usually classified on the basis of the location of the meatus (distal portion of the shaft, midshaft, proximal portion of the shaft; penoscrotal, scrotal, perineal). This classification, however, is not sufficient to explain the complexity of the defect. Because of this, a new classification scoring system called the *GMS score* (glans, meatus, shaft) has been used that includes a scale of 1–4 for each component (glans size and urethral plate quality; meatal location; and degree of shaft curvature), with the more unfavorable characteristics assigned higher scores. This new scoring system provides a means by which hypospadias severity can be standardized and surgical outcomes better classified (Merriman et al., 2013; Arlen et al., 2015).

Hypospadias is usually repaired at 6–18 months of age, with the more severe repairs postponed until after the age of 1 year (American Academy of Pediatrics, 1996). A two-stage repair is advocated for those with severe hypospadias and chordee (Fig. 88.8). If the phallus is small, testosterone injections may be given to increase phallic size, but some have found that adjuvant therapy is an independent risk

• **Fig. 88.8** Severe scrotal hypospadias with chordee. The opening is in between the scrotal folds.

factor, with higher complication rates (Wong and Braga, 2015). Poor response to testosterone injections may reveal children with androgen insensitivity (Snodgrass et al., 2014). Complication rates are reported as being 2%–5% for distal hypospadias and in excess of 30% for proximal hypospadias (Snodgrass et al., 2010; Long and Canning, 2016; Pippi Salle et al., 2016).

Other Penile Anomalies

Webbed Penis

Webbed penis, also called *penis palmatus* or *penoscrotal fusion*, is a congenital condition where the scrotal skin extends to the ventral penile shaft with deficient ventral penile shaft skin. The penile shaft may be buried in the scrotum. Usually the urethral meatus and the penile shaft are normal (Perlmutter and Chamberlain, 1972).

These infants should not be circumcised and should be referred to a specialist for repair at around 6 months of age. Repair will include use of the foreskin to cover the ventral penile shaft and recreation of the penoscrotal and penopubic junction (El-Koutby and El Gohary, 2010).

Buried Penis

Buried penis, also known as *hidden penis*, is a congenital condition where the penis is partially or completely hidden below the surface of the skin. It can sometimes lead to obstruction with ballooning of the foreskin during voiding.

These children should not be circumcised at birth and should be referred to a specialist at around 6 months of age for possible repair (Maizels et al., 1986; Wollin et al., 1990).

Micropenis

This is a congenital condition defined as a male with normal internal and external genitalia with a stretched penile length 2.5 standard deviations below the mean (Table 88.1). The reported incidence of this condition is 1.5 in 10,000 male births (Hatiboğlu and Kurtoglu, 2013).

TABLE 88.1 Stretched Penile Length by Age

| Age | Mean (cm) | SD (cm) | Mean – 2.5 SD (cm) |
|----------------------------|-----------|---------|--------------------|
| Preterm newborns, 30 weeks | 2.5 | 0.4 | 1.5 |
| Preterm newborns, 34 weeks | 3.0 | 0.4 | 2.0 |
| Term newborn | 3.5 | 0.4 | 2.5 |

SD, Standard deviation.

Aphallia

Agenesis of the phallus is very rare and occurs in 1 in 10 million to 1 in 30 million live births. This suggests an early embryologic failure in development of the genital tubercle. The urethra is located in the perineum (Skoog and Belman, 1989). The karyotype is mostly 46XY, but females have been described with absence of corporal bodies (Friedman et al., 2016a). These conditions have been reported with other anomalies, such as renal agenesis, horseshoe kidney, skeletal and neural disorders, and imperforate anus. Male children were previously raised as females, but this practice has been abandoned. These children have normal testicles, with normal testosterone production and normal spermatogenesis, and should be raised as males. With improvements in phallic reconstruction and in vitro fertilization, these patients could father children and have the potential of having a functional phallus (Macedo et al., 2015).

Epispadias

This condition is usually associated with bladder exstrophy but can appear as an isolated defect. The incidence is around 1 in 117,000 males and 1 in 150,00 to 1 in 300,000 females (Frimberger, 2011). Epispadias is characterized by failure of the urethral plate to tubularize on the dorsum, with a defect ranging from the glandular to the phallopubic location. Male patients also have dorsal curvature or chordee where females have a bifid clitoris (Grady and Mitchell, 2002).

Those with the more proximal defects (penopubic) are incontinent because of incompetence of the bladder neck, but urinary incontinence has also been reported in the more distal defects (Canon et al., 2008; Surer et al., 2000).

There are different techniques for repairing this defect, with the proximal defects also requiring a bladder neck reconstruction for continence (Mitchell and Bagli, 1996; Surer et al., 2000). The current recommendation is to delay repair of these defects until 3–6 months of age. The more proximal defects (penopubic) will also require a bladder neck reconstruction including pelvic osteotomies to place the bladder neck area in an anatomically correct location, deep in the pelvis.

Urethral Duplication

This is an uncommon anomaly and can present as a complete or partial duplication. It is more common in males than in females. The two urethras are oriented in an anteroposterior plane, with the ventral urethral meatus being the functional urethra and the dorsal urethra being stenotic (Pippi Salle et al., 2000).

In females, urethral duplication may accompany cloacal anomalies and is usually associated with duplication of the bladder, with the urethral openings being on either side of the common urogenital sinus (Pippi Salle et al., 2000).

Differences in Sex Development

This is discussed in a separate chapter. These patients pose a difficult diagnostic and therapeutic challenge and require a multidisciplinary approach to evaluation and management, including genetics, urology, gynecology, endocrinology, social work, and pediatric psychiatry.

Any phenotypically looking male, even if completely masculinized, with bilateral nonpalpable gonads should be evaluated for CAH. Failure to do so may result in an Addisonian crisis due to salt-losing adrenogenital syndrome.

Phimosis

The prepuce forms as a roll of epithelium that fuses ventrally at the frenulum. Incomplete formation of the prepuce is associated with other penile anomalies such as hypospadias, chordee, and epispadias. Once formed, the inner preputial surface fuses with the glans epithelium and may not separate from it until later in childhood. In the process of separation, cystic spaces between the two layers may form and fill with desquamated epithelium that form white beads or infantile smegma. These may be quite large and present as a mass under the foreskin. They eventually drain spontaneously.

Current recommendations are to allow the foreskin to separate from the glans and to consider management if the phimosis does not resolve during childhood or by 5–7 years of age. Forceful retraction of the foreskin is contraindicated as this produces tears in the foreskin that will result in scarring that leads to pathologic phimosis and also to inflammation and infection (posthitis).

The benefits of circumcision at birth have been the subject of debate and controversy. An American Academy of Pediatric statement states that circumcision may have benefits in reducing the risk of urinary tract infections (UTIs) and sexually transmitted diseases (American Academy of Pediatrics Task Force on Circumcision, 2012). On the other hand, the Canadian Pediatric Society concluded that since the benefits do not exceed the risks, circumcision should be performed only in boys in high-risk populations or circumstances (Brian et al., 2016).

The most common complications of newborn circumcision include bleeding, infection, formation of penile adhesions between the skin and the glans, and incomplete circumcision. Other less common complications include iatrogenic amputation of the glans, loss of penile skin, and injury to the urethra (Friedman et al., 2016b).

When newborn circumcision is being discussed with the parents, it is important to discuss the pros and cons of circumcision, including the possible benefits, risks, and complications.

Testicular Tumors

There is a bimodal age distribution for the incidence of testis tumors, with one peak occurring during the first 2 years of life and a second, larger peak occurring in young adulthood. The incidence of pediatric testis tumors is 0.5–2.0 per 100,000 children, accounting for only 1%–2% of all pediatric tumors (Coppes et al., 1994).

Teratomas are the most common benign tumors in prepubertal patients. The median age of presentation is 13 months, with several reported cases in the neonatal period (Levy et al., 1994; Grady et al., 1997). Testis-sparing surgery is a consideration for prepubertal children, but frozen sections should be obtained to confirm the diagnosis. Orchiectomy is necessary if the entire testicle is involved.

Testicular Torsion

This is a rare event, and its management is controversial. The newborn presents with swelling of the hemiscrotum with or without discomfort. In this condition the testicle, epididymis, and tunica vaginalis twist around the spermatic cord (extravaginal torsion). This condition may be unilateral or bilateral, and the bilateral torsion can either be synchronous or asynchronous (Riaz-UI-haq et al., 2013).

The cause is unknown, but it is theorized that complicated pregnancies and vaginal delivery are predisposing factors (Riaz-UI-haq et al., 2013).

The presentation depends on when the torsion occurred. If it occurred several days before birth, the newborn will have a firm painless scrotal mass. If it occurred hours before birth, the newborn usually has a painful, enlarged, and high-riding testicle (Riaz-UI-haq et al., 2013).

Diagnosis is usually made by physical examination and Doppler testicular ultrasonography showing no blood flow to the testicle.

Management of neonatal testicular torsion is controversial. Because of the low salvage rate, some advocate conservative management (Kaye et al., 2008). Most pediatric urologists today advocate immediate surgical exploration. The rationale behind this recommendation is that viability of the testicle can be assessed only surgically. Moreover, there is an increased risk of asynchronous torsion in the first month of life, and fixing the normal testicle in place will prevent it from experiencing torsion (Yerkes et al., 2005).

Urinary Tract Infections

UTIs are more common in male infants, with a male-to-female ratio of around 3:1. Uncircumcised male infants appear to be at increased risk of UTIs in the first few months of life. Uncircumcised males have a 4.1% incidence of UTIs during the first year of life, while females have a 0.5% incidence and circumcised males a 0.2% incidence. The periurethral area was found to be more frequently and more heavily colonized with uropathogens, especially *Escherichia coli*, in uncircumcised infants compared with circumcised infants (Schoen et al., 2000; Singh-Grewal et al., 2005).

Newborns with culture-documented urinary tract infection should be evaluated with at least a renal ultrasound. Some advocate a VCUG. If the ultrasound findings are abnormal, a VCUG should be performed.

Myelodysplasia

The birth prevalence of spina bifida in the United States is approximately 30 cases per 100,000 live births. The urinary tract is involved in most children with myelomeningocele. Increased bladder pressures and impaired bladder function due to the neurologic deficit eventually result in hydronephrosis and ultimately renal damage. The goal of treating children with myelomeningocele is preventing upper tract deterioration.

In utero closure of myelomeningocele has resulted in reduced need for shunting and improved motor outcomes (Adzick et al., 2011). Prenatal surgery, however, did not significantly reduce the need for clean intermittent catheterization but was associated with reduced bladder changes (Brock et al., 2015).

All children should be evaluated with a renal ultrasound.

Urodynamic studies are currently recommended early in life to risk stratify children into those at high risk of renal damage (those with high pressure bladder, high leak point pressures,

dyssynergic voiding) and those at low risk (normal bladder compliance, low leak point pressure) (Bauer et al., 2015).

An indwelling catheter is placed in the immediate postclosure period, and clean intermittent catheterization is implemented every 3–4 hours. If the catheterization volumes are low, clean intermittent catheterization can be stopped. Parents should be taught to perform clean intermittent catheterization (Wu et al., 1997). Although controversial, early initiation of clean intermittent catheterization may decrease the need for future reconstruction such as bladder augmentation (Snow-Lisy et al., 2015).

These children should be treated by a multidisciplinary team that includes neurologists, neurosurgeons, urologists, and orthopedic surgeons.

Prune-Belly Syndrome

Prune-belly syndrome, also known as *Eagle-Barrett syndrome*, is a rare defect occurring in about 1 in 40,000 births (Fig. 88.9). This abnormality is usually characterized by the triad of abdominal wall deficiency, cryptorchidism, and dilatation of the urinary tract, including severe hydronephrosis, bladder distension, and urethral dilatation (Woods and Brandon, 2007).

Prognosis ranges from death in utero to near normal life expectancy. Management of the disorder depends on the severity of the symptoms. Patients with incomplete bladder emptying and recurrent UTIs may require a vesicostomy. All male children will have to undergo bilateral orchiopexy before the age of 1 year. Some children will require urinary tract reconstruction and reconstruction of the abdominal wall (Wheatley et al., 1996).

Anorectal Malformation

Children with anorectal malformations have a higher incidence of other organ system anomalies known as *VACTERL association* (vertebral, anorectal, cardiac, tracheal, esophageal, renal and/or radial, and limb). Urologic anomalies are frequently seen and can result in severe renal impairment if treated inadequately. The most common renal anomalies seen are hydronephrosis and VUR (Wiener and Keisewetter, 1973; Goossens et al., 2011).

All children should undergo a renal and bladder ultrasound and, if the findings are abnormal, a VCUG. Sacral X-rays and ultrasound of the spine will further detect defects of the spinal cord that may also affect bladder function and cause renal impairment (Wiener and Keisewetter, 1973; Goossens et al., 2011).

Female Genital Anomalies

Female Genital Tract Development

The female reproductive system is formed by the müllerian or paramesonephric ducts. The process is complex and involves many genes. Mostly because of the absence of müllerian inhibiting substance (produced by the testicle), there is involution of the wolffian ducts. The müllerian ducts form lateral to the wolffian duct at around 6–8 weeks' gestation. The müllerian ducts then migrate medially, fuse in the midline, and are incorporated into the urogenital sinus to form the uterovaginal canal by the 10th week of gestation. The vagina forms from the fused müllerian ducts and the urogenital sinus. The upper four-fifths of the vagina is müllerian derived, and the lower fifth is of urogenital sinus in origin.

The external genitalia differentiate during the 12th to 16th weeks. The genital tubercle forms the clitoris, the urethral folds

• **Fig. 88.9** The classic wrinkled abdominal wall seen in prune-belly syndrome is accompanied by bilateral undescended testes (A). Affected patients will have marked hydronephrosis. In severe cases as illustrated here, these small kidneys may have a markedly dysmorphic sonographic appearance (B), and renal insufficiency may be present from the beginning. In cases with severe renal insufficiency, pulmonary development may be compromised, as evident on the radiograph (C); the patient required prolonged mechanical ventilation in the neonatal period.

become the labia minora, and the genital swellings become the labia majora (Masse et al., 2009).

Hydrocolpos and Hydrometrocolpos

Congenital hydrocolpos is an uncommon disorder characterized by vaginal distension with fluid. Hydrometrocolpos is associated with accumulation of fluid in both the vagina and the uterus. It is believed to be due to increased secretion by cervical mucous glands secondary to maternal hormone stimulation that expands and builds up into a pelvic mass because of vaginal outlet obstruction (Nazir et al., 2006).

Hydrocolpos can be associated with genitourinary anomalies such as persistent urogenital sinus and cloacal anomalies (Bischoff et al., 2010; Levitt and Peña, 2010; Fig. 88.10). Vaginal atresia can be associated with several syndromes (e.g., McKusick–Kaufman syndrome and Bardet–Biedl syndrome).

The most common complication of hydrocolpos is compression of the bladder, leading to urinary retention and hydronephrosis, which can ultimately cause kidney damage (Nazir et al., 2006). This can be prevented by drainage of the accumulated fluid.

If the hydrocolpos is secondary to an imperforate hymen, incision with drainage is performed. If, on the other hand, the hydrocolpos is due to vaginal atresia or cloacal anomaly, drainage of the vagina

can be accomplished either by clean intermittent catheterization or a transabdominal vaginostomy performed by an interventional radiologist under ultrasound guidance, which enables real-time evaluation without radiation exposure. The transabdominal drainage of hydrocolpos with an indwelling tube is more preferred than transvaginal drainage to prevent reaccumulation. In general, infants with hydrocolpos and urogenital sinus have increased risk of sepsis due to collection of urine in the vaginal vault. There have been reported deaths due to sepsis associated with hydrocolpos.

Vaginal Agenesis

Vaginal agenesis (Mayer–Rokitansky–Küster–Hauser syndrome) occurs in 1 in 4000 to 1 in 5000 live female births and is due to failure in canalization of the vaginal plate. Most of these patients present later in life with amenorrhea with normal secondary female sex features. The ovaries and external genitalia are normal, and the uterus may be rudimentary. Associated genitourinary abnormalities are common, such as renal agenesis and renal ectopia. Skeletal malformations are also common, particularly spine and rib anomalies. These have been termed *MURCS* (müllerian duct aplasia, renal aplasia, and cervicothoracic somite malformations). Surgical correction and timing are individualized on the basis of the extent of atresia and development of the uterine and vaginal remnants.

• **Fig. 88.10** This genitogram, performed by retrograde injection of contrast medium into a single sinus anterior to the patient's rectum, demonstrates the anteriorly placed bladder (B) and posteriorly placed vagina (V). The vagina and urethra merged into a common sinus, which then traveled a distance of 2 cm before emerging on the perineal body. The rectum (R) was normally placed. The vagina distended as a result of urinary entrapment, and the patient presented with a lower abdominal mass.

Cloacal Anomalies and Urogenital Sinus

A common urogenital sinus is a normal part of development of the fetus. If müllerian duct development stops during the first trimester, a common urogenital sinus will persist at birth. The confluence of the vagina into the common channel varies and depends on when the development arrest occurred. The earlier the arrest, the higher the connection of the vagina will be. The anus will be normally located but sometimes is anteriorly displaced. On examination, only one opening is found in the introitus, and there is a second, anal opening.

Sometimes the vagina is distended, with urine causing compression of the ureters and hydronephrosis. This can be easily managed

with initiation of intermittent catheterization, which will decompress the distended vagina (Rink and Cain, 2008).

Evaluation includes an examination of the patient under anesthesia and determination of the length of the common channel and the length of the urethra from the bladder neck to the common channel. A cloacogram with three-dimensional CT reconstruction will also provide details of the anatomy, which aids in surgical planning. Surgical repair is usually undertaken during the first year of life, and the reconstruction depends on the confluence of the vagina into the urogenital sinus (Patel et al., 2012; Valentini et al., 2016).

A cloacal anomaly is defined when the urogenital sinus is combined with an anorectal malformation. These infants have only one opening into the perineum and confluence of the vagina, rectum, and urethra into a common channel (Bischoff et al., 2010; Levitt and Peña, 2010; Peña, 2016). These children require a colostomy for stool divergence, and at the same time an examination under anesthesia can be performed to determine the extent of the common channel and the length of the urethra and vaginal channels. The reconstruction is usually performed at around 6–8 months of age or when the child is nutritionally stable. Multiple teams are involved in the reconstruction, including pediatric general surgery, pediatric urology, and pediatric gynecology teams.

Müllerian Duplication Anomalies

If fusion of the müllerian duct is incomplete, duplication anomalies occur. This can range from a septate vagina to vaginal duplication, where one or both vaginas are open to the perineum. These children may have a uterus that is partially fused (bicornuate uterus) to complete duplication with two cervixes (uterus didelphys) (Acien and Acien, 2016).

Introital Masses in Children

These are seen on physical examination of the infant, and the differential diagnosis includes:

- Imperforate hymen
- Prolapsed ureterocele
- Urethra prolapse
- Skene or Gartner duct cysts
- Rhabdomyosarcoma (Nussbaum and Lebowitz, 1983)

Clinical Evaluation of Renal and Urinary Tract Disease

CARLTON M. BATES AND ANDREW L. SCHWADERER

KEY POINTS

- Renal anomalies are identified in 0.5% of pregnancies and account for 20% of all identified prenatal anomalies.
- Hydronephrosis (abnormal increase in the fetal renal pelvic diameter) is the most common identified renal anomaly.
- Oligohydramnios should prompt an evaluation for severe, bilateral, poorly functioning, or absent kidneys.
- Fetal magnetic resonance imaging may be useful as a complementary imaging modality when ultrasound results are inconclusive.
- Prenatal intervention strategies that improve long-term kidney and urinary tract outcomes remain in need of ongoing research.
- Monogenic gene disorders account for a significant number of structural and/or glomerular kidney disorders identified in infants.
- Palpable abdominal masses in neonates most often originate from the urinary tract and are commonly cystic or obstructive.
- Absolute/corrected glomerular filtration rate is much lower in newborns than in older children and adults.

Prenatal Evaluation of Renal and Urinary Tract Disease

Prenatal Diagnosis

Renal anomalies will be frequently encountered in neonatal practice as they are identified in 0.5%–5% of pregnancies and account for 20% of all anomalies diagnosed with prenatal imaging (Scott and Renwick, 1988; Scott, 2002). Disorders of the renal and urinary tract include a broad spectrum of clinical entities with a wide variation of severity. This variation may result in challenging clinical diagnosis and management scenarios. Thus an understanding of the clinical evaluation in the prenatal and neonatal periods is an essential component of neonatal clinical practice.

Prenatal Renal Ultrasound

The primary tool utilized in the diagnosis of disorders of the renal and urinary tract is the prenatal ultrasound. Although the kidneys may be visualized at 10 weeks' gestation, accurate determination of renal anatomy is usually not possible until 16 weeks' gestation (Stamilio and Morgan, 1998). Findings on a prenatal ultrasound

that suggest renal or urinary tract disease include hydronephrosis, renal cysts, hyperechoic kidneys, renal mass, oligohydramnios, and polyhydramnios. Hydronephrosis (abnormal increase in the fetal renal pelvic diameter) is the most common identified renal anomaly, affecting 1%–5% of all pregnancies (Dicke et al., 2006; Nguyen et al., 2010). The presence of prenatal hydronephrosis may indicate a variety of renal disorders including vesicoureteral reflux, upper urinary tract obstruction (ureteropelvic junction obstruction, ureterovesical junction obstruction, and obstructive megaureter), and lower urinary tract obstruction (posterior urethral valves and prune belly syndrome) (Stamilio and Morgan, 1998; Yee and Wilcox, 2008). While mild hydronephrosis is often transitory and not associated with sequelae, higher degrees of hydronephrosis, early onset of hydronephrosis (first trimester), hydronephrosis that worsens with time, and bilateral hydronephrosis are usually associated with more severe disease, such as posterior urethral valves in male fetuses (Yee and Wilcox, 2008; Nguyen et al., 2010). Prenatal renal cysts can be seen with autosomal dominant polycystic kidney disease (ADPKD), multicystic dysplastic kidneys, cystic renal dysplasia, or obstructive dysplasia (Stamilio and Morgan, 1998; Avni et al., 2012). Hyperechoic kidneys are often associated with overt cysts as in ADPKD, with microscopic cysts (autosomal recessive polycystic kidney disease [ARPKD], Bardet–Biedl syndrome, Meckel–Gruber syndrome, hepatocyte nuclear factor 1 β [HNF1 β] mutations, or nephrotic syndrome), or renal dysplasia (Chaumoitre et al., 2006; Avni et al., 2012). The cause of oligohydramnios is multifactorial; however, its presence can indicate decreased fetal urine output and renal function (Kemper and Mueller-Wiefel, 2007). Oligohydramnios should prompt an evaluation for severe, bilateral, poorly functioning or absent kidneys as can be seen with renal agenesis, renal dysplasia, ARPKD, and lower urinary tract obstruction (Kemper and Mueller-Wiefel, 2007; Deshpande and Hennekam, 2008). Polyhydramnios is caused by renal anomalies in a small percentage of cases but can indicate the presence of a renal concentrating defect associated with renal dysplasia, nephrotic syndrome, or inherited renal tubular defects (Cole and Quamme, 2000; van Eijk et al., 2002; Deshpande and Hennekam, 2008). Congenital renal tumors are rare, and most are benign. The most common tumor is the mesoblastic nephroma, which is a benign tumor appearing as a unilateral single solid mass on prenatal ultrasound in the third trimester (Giulian, 1984; Cho and Lee, 2014; Do et al., 2015). Neuroblastomas are the most

• **Fig. 89.1** Coronal (A) and axial (B) images of fetal kidneys on T2-weighted magnetic resonance imaging. Note the normal right kidney (arrows) and large multicystic dysplastic left kidney (arrowheads) with the hyperintense peripheral cyst.

common fetal malignant tumors, appearing in the third trimester most often on the right side and suprarenal in location (Cho and Lee, 2014).

Fetal Magnetic Resonance Imaging

An emerging adjunct therapy to ultrasound is fetal magnetic resonance imaging (MRI). The typical indication for fetal urinary tract MRI evaluation is a second or third trimester pregnancy with oligohydramnios and/or an inconclusive prenatal renal ultrasound (Poutamo et al., 2000; Abdelazim and Belal, 2013). Fetal MRI lends additional insight into the evaluation of renal cysts and renal agenesis and can clarify diagnoses that would have been missed by ultrasound alone (Abdelazim and Belal, 2013). Differentiating renal cysts from a dilated collecting system is often problematic; the detailed anatomy provided by MRI can help determine if the apparent cysts are limited to the periphery (consistent with cyst) (Fig. 89.1) or central in location (consistent with a dilated collecting system) (Hormann et al., 2006). An increase in signal intensity in the renal cortex can differentiate between ARPKD and other polycystic diseases, which can have a similar hyperechoic appearance on ultrasound (Liu et al., 2006). When oligohydramnios is present and the kidneys cannot be conclusively identified on ultrasound, an MRI is effective at identifying an empty renal pouch, underlying changes (renal dysplasia), or ectopic kidneys (Hormann et al., 2006). Comparison of kidney and urinary tract fetal MRIs and ultrasounds reveals that MRI is able to identify abnormalities not identified by ultrasound in 26%–31% of patients (Cassart et al., 2004; Gupta et al., 2010; Behairy et al., 2015). Therefore fetal MRI may be very useful as a complementary imaging modality when ultrasound results are inconclusive. In addition to providing more detail of the renal and urinary tract anatomy, MRIs are also useful in measuring the amniotic fluid, evaluating bladder filling, and assessing lung maturation (Hormann et al., 2006). The aforementioned findings are indirect measures of kidney function that can help define the degree of renal impairment. While not yet available clinically, MRI has been shown in animals and in

postmortem human kidneys to accurately assess glomerular number (Puelles and Bertram, 2015).

Amniotic Fluid and Chorionic Villus Sampling

The diagnosis of most genetic disease with renal and urinary tract manifestations is based on the characteristic multiorgan findings on imaging. With an increasing number of conditions, analysis of DNA or tissue from amniocentesis or chorionic villus biopsy can be utilized to confirm a suspected disorder or determine prognosis. Examples include:

- Molecular testing for the mutations in genes for suspected congenital forms of nephritic syndrome (in fetuses with polyhydramnios and hyperechoic kidneys) by chorionic villus sampling in fetuses. Studies have shown that up to 84% of congenital forms of nephrotic syndrome are caused by mutations in *NPHS1*, *NPHS2*, *WT1*, or *LAMB2A* genes (see later) (Hinkes et al., 2007; Deshpande and Hennekam, 2008).
- Fetal karyotyping by amniocentesis or chorionic villus sampling performed when kidney defects occur with anomalies of other organ systems can be used to identify the precise chromosome anomaly and the likely genetic causes for the disorders (Deshpande and Hennekam, 2008; Chen et al., 2013; Li et al., 2014).
- Beckwith–Wiedemann syndrome, which can be associated with Wilms tumor and other renal anomalies, can be diagnosed by specific 11p methylation studies in amniotic fluid (Deshpande and Hennekam, 2008).
- Historically, most cases of prenatally enlarged echogenic kidneys were thought to be due to ADPKD, ARPKD, and cystic dysplasia. Microarray comparative genomic hybridization (CGH) arrays have demonstrated that other conditions, including deletions of 17q12, which includes *HNF1B*, are also responsible for some prenatally enlarged echogenic kidneys (Jones et al., 2015). Subsequently, prenatal CGH arrays have been proposed for echogenic kidneys with an unknown cause (Jones et al., 2015).
- While not yet available clinically, panels of peptides, extracellular vesicles, and exosomes containing CD24 in amniotic fluid have

been shown to be more predictive of more severe forms of congenital urinary tract obstruction than imaging alone (Chevalier, 2015).

- Hypotonic fetal urine, characterized by a sodium level of less than 90 milliequivalent (mEq)/L, chloride less than 80 mEq/L, and osmolality less than 180 mOsm/L in patients with bilateral hydronephrosis and no evidence of renal dysplasia, is associated with a good prognosis, particularly if present on sequential samples taken 48–72 hours apart (Johnson et al., 1995; Wu and Johnson, 2009).

Prenatal Management of Renal and Urinary Tract Disease

Goals of Management and Prognostic Factors

Identification of renal and urinary tract disease on prenatal screening provides the basis for formulating a differential diagnosis, determining prenatal and postnatal risks, and screening for other anomalies. The goals of prenatal intervention include the preservation of renal function and the promotion of lung maturation (Yiee and Wilcox, 2008). Potential management options include parental counseling, follow-up or serial prenatal imaging, postnatal imaging (ultrasound, voiding cystourethrogram [VCUG] etc.), fetal interventions, and early multispecialty collaboration (Pates and Dashe, 2006; Yiee and Wilcox, 2008; Swords and Peters, 2015). Factors associated with a poor outcome include bilateral involvement of the kidneys and oligohydramnios. If oligohydramnios is severe the oligohydramnios sequence can occur. This is characterized by pulmonary hypoplasia, “flattened” face, “squashed” nose, and positional limb abnormalities (Deshpande and Hennekam, 2008). When oligohydramnios is present the prognosis may vary based upon the underlying renal diagnosis. The prognosis for bilateral renal aplasia is usually much less favorable than if the oligohydramnios is secondary to obstruction (Cendron et al., 1994; Kemper and Mueller-Wiefel, 2007; Schwaderer et al., 2007).

Interventions

The effectiveness of fetal intervention for hydronephrosis is controversial (Hubert and Palmer, 2007). The primary procedure is placement of a vesicoamniotic shunt with the goals of relieving the obstruction (potentially preventing further renal damage) and decreasing oligohydramnios (Wu and Johnson, 2009). This procedure may be considered when bladder outlet obstruction is present, the life of the neonate is at risk, the fetus would likely benefit from bladder decompression, the pregnancy is singleton, and the fetus has a normal karyotype (Hubert and Palmer, 2007). A multicenter prospective study aimed at determining therapeutic and cost effectiveness of vesicoamniotic shunting in fetuses with suspected obstruction was terminated early due to poor enrollment but did show some modest increases in survival at 28 days and 1 year of age over conservative management; unfortunately, survival and renal function were relatively poor in both groups, and costs were higher in the shunted group than in the conservative treatment group (Morris et al., 2013). It is a matter of debate as to whether amniocentesis prevents or decreases pulmonary hypoplasia. Some reports have suggested a benefit for oligohydramnios secondary to premature rupture of membrane (De Carolis et al., 2004; Klaassen et al., 2007), and others have reported long-term success with serial amniocentesis in patients with bilateral renal aplasia (Bienstock et al., 2014). Rarely, fetal surgery is indicated for removal of tumors,

such as aggressive subsets of neuroblastomas (Bruny and Crombleholme, 2013). In utero repair of myelomeningocele has been proposed as a strategy to improve bladder function. Compared with postnatal myelomeningocele repair, prenatal repair results in less bladder trabeculation but does not reduce the need for clean intermittent catheterization at 30 months of age (Brock et al., 2015). Prenatal intervention strategies that improve long-term kidney and urinary tract outcomes remain an area in need of ongoing research.

Postnatal Evaluation of Renal and Urinary Tract Disease

Prenatal and Perinatal History

As noted earlier, a history of oligohydramnios is often associated with poor urine flow and poor kidney function. Forms that occur in the first trimester (e.g., bilateral renal aplasia or severe dysgenesis) are often associated with poor prognoses, in part from poor pulmonary development. Other causes such as obstructive nephropathy may have a more favorable outcome (Kemper and Mueller-Wiefel, 2007). As noted earlier, polyhydramnios is often idiopathic or secondary to nonrenal problems such as gastrointestinal or central nervous system abnormalities (Deshpande and Hennekam, 2008) but is associated with renal anomalies such as infantile Bartter syndrome and nephrogenic diabetes insipidus. A large placenta (>25% of the birthweight) can be a sign of congenital nephrotic syndrome (Holmberg et al., 1996). Hypoxia–ischemia (e.g., perinatal anoxia, placental abruption), nephrotoxin exposure (e.g., pre/perinatal use of nonsteroidal antiinflammatory agents, aminoglycosides, angiotensin-converting enzyme inhibitors/angiotensin receptor blockers), and shock (e.g., blood loss, sepsis) increase the risk of acute kidney injury (AKI), which has an incidence of over 20/100,000 neonatal patients (Andreoli, 2004; Askenazi et al., 2009; Selewski et al., 2015). Studies in very low birth weight infants have reported 12%–40% rates of AKI that then confer much higher risks of mortality above those patients without AKI (Selewski et al., 2015).

Family History

Renal structural diseases such as aplasia, dysplasia, and multicystic dysplastic kidneys in parents or siblings increase the risks of congenital kidney disease in newborn patients (Roodhooft et al., 1984; Belk et al., 2002; Schwaderer et al., 2007). Mutations in many genes (e.g., *HNF1B*, *PAX2*, or *EYA1*) account for a large number of autosomal dominant inherited forms of either isolated structural kidney disease or as part of syndromes with extrarenal manifestations (Madariaga et al., 2013; Hwang et al., 2014). Some forms of PKD, vesicoureteral reflux, and medullary cystic kidney disease follow autosomal dominant inheritance patterns; thus screening should be considered in neonates whose parents have these disorders. Appropriate screening would be indicated in neonates whose siblings have autosomal recessive diseases (e.g., autosomal recessive PKD, cystinosis) or X-linked diseases (e.g., Alport disease or Lowe syndrome).

Physical Examination

Hypertension

As discussed in Chapter 93, increased blood pressure in the neonatal period is frequently secondary to renovascular and/or parenchymal disorders and should receive appropriate evaluation.

Micturition

Frequently, healthy neonates will not void until 12 hours or later after birth, although nearly all will produce some urine by 24 hours (Clark, 1977). Once voiding commences, it almost never occurs during sleep in term infants, whereas 60% of preterm infants will void when asleep; furthermore, both term and preterm neonates tend to void frequently (often hourly) with quite variable volumes (Sillen, 2001; Sillen and Hjalmas, 2004). Male preterm and full-term neonates have greater postvoid residual volumes and decreased bladder emptying rates than their female counterparts, likely because of the need for higher voiding pressures due to the longer male urethra (Wen et al., 2014). Delayed voiding (beyond 24 hours after birth) is often seen after stressful deliveries and has been correlated with enhanced arginine vasopressin and aldosterone secretion (Vuohelainen et al., 2008). Prolonged absence of urine formation should prompt evaluation for AKI or structural kidney/urinary tract disease.

Abdominal Masses

Palpation of the abdomen for masses is best performed within the first few days after birth, during which time there is relative hypotonia of the abdominal musculature (Perlman and Williams, 1976). Palpable abdominal masses, particularly flank masses, in neonates most often originate from the urinary tract and are commonly cystic or obstructive (Chandler and Gauderer, 2004; Ranganath et al., 2012). Among three studies that each enrolled over 10,000 newborns, the incidence of renal/urinary tract anomalies detected by deep palpation ranged from 0.2%–0.6% (Chandler and Gauderer, 2004). The most common urinary tract anomalies detected as abdominal masses are hydronephrotic kidneys, followed by multicystic dysplastic kidneys (Chandler and Gauderer, 2004). Bilateral flank masses may be palpated in patients with autosomal recessive PKD. Although less common, neonatal tumors of renal origin are usually not detected prenatally (Shapiro, 2014). The most common neonatal renal tumors are congenital mesoblastic nephromas (typically benign), followed by Wilms tumor (which is usually diagnosed after 6 months of age), rhabdoid tumors, and clear cell sarcomas (Chandler and Gauderer, 2004; Glick et al., 2004; Shapiro, 2014). While rarely originating in the kidney or lower urinary tract, neuroblastomas are the most common neonatal malignancy, accounting for greater than 20% of neonatal tumors (Shapiro, 2014). An abdominal mass should be evaluated by appropriate laboratory and imaging studies (see later).

Edema

Edema occurs when there is an imbalance between capillary hydrostatic and interstitial oncotic forces. Neonatal edema is more commonly seen in preterm infants than term infants and is often transient, resolving a few days after birth (Griffiths, 1959; Cartledge and Rutter, 1986; Hahn et al., 1997). Most cases of persistent pathologic edema, including cases of nonimmune fetal hydrops (which includes edema and ascites) are extrarenal in origin (Bellini and Hennekam, 2012). The major renal causes include total body fluid overload secondary to a decrease in glomerular filtration rate (GFR) (from acute or chronic renal injury) and low intravascular oncotic pressure from urinary protein losses (from congenital nephrotic syndrome, see later).

Ascites

As with edema, ascites can arise as an imbalance between hydrostatic and oncotic pressures, but it can also occur secondary to decreased

lymphatic drainage. Although neonatal ascites is somewhat rare, urinary tract abnormalities account for a significant number of cases (Aslam et al., 2007; Griscom et al., 1977). The most common urinary tract cause is urinary ascites, which can result from perforation of the ureter, renal pelvis, or bladder from obstruction (e.g., posterior urethral valves) or, less commonly, from a persistent urogenital sinus (Loganathan et al., 2014). Less common conditions leading to ascites are congenital nephrotic syndrome and renal vein thrombosis.

Laboratory Tests

Serum Estimates of Glomerular Filtration Rate

Absolute and relative (corrected for body surface area) GFR is much lower in newborns than older children and adults; at day 1 of life, GFR may be as low as 30 mL/min per 1.73 m² in term infants (and even lower in preterm infants) rising to about 50 mL/min per 1.73 m² by 1 month of life and 75 mL/min per 1.73 m² by 2 months of life (Arant, 1987; Chevalier, 1996). Because of technical difficulties with 24-hour urine collections for clearance measurements and/or the use of exogenous agents that are freely filtered at the glomerulus, most often assays of endogenous serum molecules are used to estimate GFR in neonates. As in adults, serum creatinine is both filtered and secreted in the kidney; however, creatinine also appears to be reabsorbed within the tubules of immature kidneys (with more reabsorption in preterm infants) (Guignard and Drukker, 1999). This likely accounts for the delay in creatinine drop that occurs from the time of birth (at which time serum creatinine reflects the mother's level) until about 7–10 days after birth in term newborns, which may extend to 3 weeks in preterm newborns (tubular reabsorption may also explain creatinine levels slightly greater than the mother's in many preterm newborns just after birth). In one study, term newborns had a mean serum creatinine of 0.85 ± 0.43 mg/dL at 2 days of age, 0.57 ± 0.40 mg/dL at 7 days of age, and 0.42 ± 0.23 mg/dL at 14 days of age (Rudd et al., 1983). In 28 weeks' gestation preterm newborns, the same study reported serum creatinine measurements of 1.31 ± 0.45 mg/dL at 2 days of age, 0.95 ± 0.36 mg/dL at 7 days of age, and 0.81 ± 0.36 mg/dL at 14 days of age. Serum cystatin C levels have some potential advantages to serum creatinine levels. For instance, unlike creatinine, cystatin C is not influenced by muscle mass and does not cross the placenta (Cataldi et al., 1999). Serum cystatin C reference values for neonates have been determined longitudinally up to 1 year of age (Nakashima et al., 2016). However, the difficulty of comparing a "gold standard" inulin or iothexol clearance in preterm infants makes determining the most accurate GFR measurement difficult. Blood urea nitrogen concentration is also often used as another indirect measure of kidney function but is less reliable than creatinine due to alterations based on protein intake and hydration status.

Other Serum Chemistries

In addition to GFR, renal tubular function often differs in the neonatal kidney from that of adults. Acidification differs with normal serum bicarbonate levels in the term neonate, ranging from 19–21 mEq/L, and in the preterm infant ranging from 16–20 mEq/L (Shaw, 2008). The lower serum bicarbonate is due to a lower threshold at the proximal tubule; the lowered threshold is likely due to the presence of different acid transporter isoforms in maturing kidneys versus adult kidneys as well as due to hormonal influences on abundance and activity of these transporters (Baum and Quigley, 1995; Baum, 2008). Serum potassium is less well

excreted in the collecting ducts of neonates compared with older children and adults, with normal newborn levels up to 6.7 mmol/L (Lorenz, 1997). This physiologic increase in potassium (to accommodate vigorous growth over the first year of life) is due to a paucity of aldosterone-sensitive secretory potassium channels and an abundance of potassium reabsorbing transporters on the luminal surface of collecting ducts (Gurkan et al., 2007). Sodium must remain in positive balance for rapidly growing neonates (despite a diet that is typically low in sodium). The ability to excrete less sodium chloride appears to be due to differences in expression of sodium/proton antiporter isoforms and tight junction proteins, called claudins, in neonates versus adults and older children (Baum and Quigley, 2004; Baum, 2008). Serum phosphate levels are also typically higher in newborns with serum levels ranging from 5.8–9.3 mg/dL on the first day of life (with the higher levels typically in preterm infants (Spitzer and Barac-Nieto, 2001; Hellstern et al., 2003)). This physiologic increase in serum phosphate levels compared with older humans (again, to accommodate rapid growth) is due to the enhanced capacity of sodium phosphate transport at the proximal tubule in neonates (Spitzer and Barac-Nieto, 2001).

Urine

Urinary Tract Infection

Most frequently, urine collections in newborn infants are performed to evaluate for suspected urinary tract infection. Evidence-based guidelines were published recently regarding evaluation for urinary tract infection (UTI) in patients from 2 months to 2 years of age (Roberts, 2011). Some of these guidelines concluded that UTI should be considered in all patients with unexplained fever and is best assessed with a urine culture. For patients under 2 months of age, suprapubic aspiration or transurethral catheterization is highly recommended when evaluating for urinary tract infections. According to the most recent American Academy of Pediatrics guidelines, a renal ultrasound should be performed in patients from 2 months to 2 years after their first confirmed UTI and a VCUG performed after the second UTI (Roberts, 2011).

Concentrating/Diluting

Compared with adults, newborns have a diminished capacity to concentrate their urine, because of their relative insensitivity to antidiuretic hormone and the presence of a less hypertonic medulla due to less sodium chloride and urea transport (Quigley et al., 2001; Bonilla-Felix, 2004). Neonates have less ability to dilute their urine compared with adults and older children, although they can handle the typically hypotonic fluids they receive for nutrition.

Proteinuria

Physiologic and pathologic proteinuria can be seen in newborns, particularly in preterm and/or low birth weight infants. Normal preterm and term infants have an average of 182 mg/m² per day and 145 mg/m² per day of total urine protein, respectively, compared with 91 mg/m² per day in children 2–4 years of age (Loghman-Adham, 1998). A recent study also found that very low birth weight infants had a higher risk of pathologic albuminuria (albumin/creatinine ratio >20 mg/g) than normal infants, particularly those that developed hypotension after birth (Iacobelli et al., 2007). Another study showed that preterm infants were more likely to develop pathologic tubular proteinuria (α 1 microglobulin/creatinine ratio >10 mg/mmol) than term infants (Ojala et al., 2006). Low gestational age enhanced the risk of early tubular proteinuria, the

highest α 1 microglobulin/creatinine ratios, and delayed normalization of proteinuria.

A more rare but serious pathologic finding is congenital nephrotic syndrome, defined as high-grade proteinuria, low serum albumin, and edema within the first year of life. The differential diagnosis includes primary/genetic causes (e.g., Finnish-type nephrotic syndrome and diffuse mesangial sclerosis) and secondary causes such as infections (e.g., cytomegalovirus, syphilis, hepatitis), genetic syndromes (e.g., Denys-Drash and Frasier syndromes), toxins/drugs, hemolytic uremic syndrome, systemic lupus erythematosus, and nephroblastoma (Papez and Smoyer, 2004). Unlike nephrotic syndrome in later childhood, congenital nephrotic syndrome usually portends a poor prognosis, including end-stage renal failure (with the exception of some infectious forms that respond to appropriate therapy). Interestingly, a classic study found that 2/3 of all cases of primary/genetic congenital nephrotic syndrome were caused by mutations in 1 of 4 genes, encoding for nephrin (major cause of Finnish type), podocin, Wilms tumor suppressor gene 1 (found in Denys-Drash and Frasier syndromes), and laminin β 2 (a cause of diffuse mesangial sclerosis) (Hinkes et al., 2007).

Other Urinary Findings (Hematuria, Hemoglobinuria, Myoglobinuria, Uricosuria)

Hematuria is a rare finding in neonates and when present has a wide differential diagnosis including renal vein thrombosis, PKD, obstructive nephropathy, tumor, congenital malformations, urinary tract infection, and AKI (Emanuel and Aronson, 1974). Hemoglobinuria, another rare finding in newborn infants, occurs secondary to intravascular hemolysis, of which the most common cause is ABO blood group incompatibility (Murray and Roberts, 2007). Myoglobinuria is even more rarely detected in neonates but has been reported secondary to rhabdomyolysis from asphyxia and shock (Sirota et al., 1988). Finally, pink or red uric acid crystals are often seen in diapers of otherwise healthy newborns; while this has been reported to be a consequence of high urine uric acid levels in normal newborns, one study challenges that contention, arguing that there must be other reasons for uric acid crystallization in these neonates (Kupeli et al., 2005). Urinary neutrophil gelatinase-associated lipocalin (NGAL) levels correlate with creatinine-based AKI (Goldstein, 2015). Additionally, urine NGAL levels above a certain threshold are associated with clinical outcomes even when measured at day 1 when newborn serum creatinine levels are representative of maternal levels (Essajee et al., 2015; Goldstein, 2015).

Imaging

Renal Ultrasound

The primary indications for renal ultrasound in the neonatal period include a palpable abdominal mass, hypertension, renal failure, or suspected malformations of the renal and urinary tract (McInnis et al., 1982). The neonatal presentation of a renal mass or renal failure is often suggested by the prenatal evaluation (Riccabona, 2006). An abdominal mass of renal etiology might appear as large kidneys, hydronephrotic kidneys, or a renal tumor. Renal ultrasound can be useful to distinguish between intrinsic, prerenal, and postrenal failure. Regarding intrinsic causes of renal failure, neonatal nephrotic syndrome and glomerulonephritis will present as large echogenic kidneys; renal vein thrombosis will present as large echogenic kidneys with renal vein color signal missing on veins with thrombosis and increased resistive indices on a duplex examination; and congenital dysplasia will present as small echogenic kidneys

(Riccabona, 2006). Postrenal failure is characterized by hydronephrosis, and prerenal failure is characterized by echogenic kidneys with decreased flow velocities with elevated resistive index values on duplex examination (Riccabona, 2006). Ultrasound imaging has been recommended as a noninvasive study that should be obtained in all hypertensive infants as it may identify correctable causes of the hypertension including renal vein thrombosis, aortic/renal artery thrombi, or anatomic renal abnormalities (Flynn, 2000). If a renal ultrasound is planned to follow-up prenatal hydronephrosis, it is advantageous to wait until day 3 of life as the initial period of neonatal oliguria might mask renal collecting system dilation (Kennedy, 2002).

Computed Tomography Scan

The risk of ionizing radiation from computed tomography (CT) is higher in neonates secondary to more radiosensitive tissues and longer life expectancies (Brenner et al., 2001). Further, the CT evaluation of the kidney is limited by reduced contrast uptake by the renal parenchyma (Olsen and Gunny, 2006). Because of the aforementioned factors, CT has limited use in the evaluation of the renal and urinary tract during the neonatal period. Nonetheless, CT does have a role when ultrasound results are inconclusive for complex anomalies of the kidney, abdominal masses, and suspected renal vascular anomalies and when MRI would be problematic due to sedation risk or a contraindication to MRI contrast (Gnanasambandam and Olsen, 2006; Olsen and Gunny, 2006; Grobner and Prischl, 2007).

Magnetic Resonance Imaging

MRI has several advantages in imaging the neonatal kidney and urinary tract. The absence of radiation and detailed anatomy of soft tissue with MRI make it an attractive tool to clearly define normal and abnormal renal anatomy when ultrasound is insufficient. However, MRI has disadvantages as sedation is sometimes necessary for infants (Michael, 2008). There are risks for MRI contrast (gadolinium)-associated nephrogenic systemic fibrosis in the immature neonatal kidney and gadolinium depositions in the bone marrow (Michael, 2008). Applications in which MRI are particularly useful include the identification of a suspected ectopic or dysplastic kidney and the identification of a renovascular cause of hypertension in neonates unable to tolerate angiography (Mustafa et al., 2006; Michael, 2008).

Voiding Cystourethrography

VCUG is utilized to evaluate for lower urinary tract obstruction and vesicoureteral reflux. In males a fluoroscopic as opposed to a nuclear VCUG should be obtained as the anatomic details of the male urethra warrant a complete evaluation (Kennedy, 2002).

Nuclear Medicine

The use of nuclear medicine is limited in neonatal practice. Two studies that might be occasionally used include DMSA cortical scintigraphy and the DTPA or MAG3 diuretic renogram. Cortical DMSA cortical scintigraphy can be used to evaluate left and right relative renal function and evaluate for acute pyelonephritis (Piepsz

and Ham, 2006). The diuretic renogram is indicated to evaluate for upper urinary tract obstruction when fetal hydronephrosis has persisted and vesicoureteral reflux has been excluded (Kennedy, 2002; Piepsz and Ham, 2006). It may also be used to identify ectopic renal tissue (Piepsz and Ham, 2006). In the future, MRI may supplant nuclear medicine studies. A 2014 study demonstrated that magnetic resonance urography was superior to DMSA scan for identification of renal parenchymal defects in a population of children with a mean age of 9 months (Cerwinka et al., 2014).

In conclusion, structural abnormalities are common causes of kidney and urinary tract disorders in the perinatal period of life. Thus imaging modalities such as renal ultrasound remain very useful tools in evaluating patients with suspected kidney and/or urinary tract disease. A careful history and physical examination will also offer insights into the underlying causes of kidney and urinary tract disorders. Finally, compared with that of older children and adults, the neonatal kidney is less efficient at clearance and has reduced tubular function (acidification, potassium secretion, sodium transport), except for phosphate, which is reabsorbed more efficiently in the very young.

Acute Kidney Injury and Chronic Kidney Disease

DAVID ASKENAZI, DAVID SELEWSKI, LAUREL WILLIG, AND BRADLEY A. WARADY

KEY POINTS

- Acute kidney injury (AKI) is common in critically ill neonates. AKI affects survival, hospital expenditures, and long-term outcomes, independent of severity of illness and comorbidities.
- Renal development continues until 34 weeks' gestation. Neonatal intensive care unit graduates, especially those with AKI, premature infants, and those with intrauterine growth retardation, are at risk for long-term chronic kidney disease (CKD).
- Clinical sequelae of CKD include anemia, acidosis, electrolyte abnormality, growth restriction, renal osteodystrophy, fluid overload, hypertension, and uremia. Attention to these complications is critical to optimizing long-term outcomes.
- Long-term survival of neonates with end-stage renal disease (ESRD) appears to be approaching that of older infants and young children, but they continue to have higher morbidity and mortality due to infectious and cardiovascular complications.
- Renal replacement therapy can be performed in neonatal patients and is likely to improve outcomes in children with AKI and those with ESRD.

Acute Kidney Injury

Acute kidney injury (AKI) is characterized by a sudden impairment in kidney function, which may result in dysregulation of fluid balance, acid–base, electrolytes, and nitrogenous waste products. AKI has supplanted the term *acute renal failure* as the accepted terminology to describe acute changes in renal function across medicine, including neonatology (Mehta et al., 2007; Selewski et al., 2015). The term *injury* highlights the spectrum of organ injury and differentiates a damaged organ from an organ that has dysfunction. The main impetus to change the terminology was to highlight early detection, as even small changes in kidney function (rise of serum creatinine [SCr] by 0.3 mg/dL) can be associated with adverse outcomes. AKI is now staged into mild, moderate, and severe, based on either the most severe oliguria or rise in SCr.

In 2005, the introduction of an empiric, categorical staged AKI definition for adults dramatically changed the field of AKI as it brought consensus and enabled comparison between studies (Hoste and Kellum, 2006). In 2007, modifications were made based on improved understanding from observational data (Mehta et al., 2007). Additional modifications occurred in 2012, and currently Kidney Diseases: Improving Global Outcomes (KDIGO) defines

AKI when there is a rise in SCr of 0.3 mg/dL over 48 hours or a decrease in urine output (UOP) occurs. The development and utilization of standardized definitions of AKI have created commonality in defining AKI and clearly show that incremental degrees of AKI independently impact survival after correcting for comorbidities, complications, and severity of illness in neonatal (Selewski et al., 2015), pediatric (Akcan-Arikan et al., 2007), and adult studies (Hoste and Kellum, 2006).

A neonatal classification of AKI used to define AKI in critically ill neonates (Table 90.1) parallels the KDIGO adult definition and uses the lowest SCr as a baseline for subsequent SCr values. In April 2013, neonatologists and pediatric nephrologists participating in the NIDDK workshop carefully scrutinized this definition. They concluded that, at that time, this definition offered a reasonable starting point and would allow for consistency throughout studies yet warned that rigorous evaluation of the definition was necessary.

Importantly, SCr-based AKI definitions do not detect kidney damage; instead they document changes in kidney function. Although SCr is the most common method of documenting changes in kidney function, it has significant shortcomings, including:

- SCr does not change until 25%–50% of the kidney function has been lost, and thus it may take 48–72 hours for SCr levels to rise after an insult (Brion et al., 1986).
- At a lower glomerular filtration rate (GFR), SCr will overestimate renal function due to tubular secretion (Brion et al., 1986).
- SCr varies by muscle mass, hydration status, sex, age, and gender.
- Different measurement methods (Jaffee reaction vs enzymatic) produce different values, and medications and bilirubin can affect SCr measured by the Jaffee method (Rajs and Mayer, 1992; Lolekha et al., 2001).
- Once a patient receives dialysis, SCr can no longer be used to assess kidney function, since SCr is easily dialyzed.

Additional problems specific to neonates with using SCr as a measure of AKI include:

- SCr measurements in the first few days of life reflect the mother's levels; thereafter, the distribution of normal SCr values varies greatly, dependent on level of prematurity and age (Gallini et al., 2000) (Fig. 90.1).
- Normal nephrogenesis in the healthy fetus continues until 34 weeks of gestation when the number of nephrons, 1.6 to 2.4 million, approximates that of an adult (Abrahamson, 1991).

Dependent on degree of prematurity, GFR steadily improves from 10–20 mL/min per 1.73 m² during the first week of life to 30–40 mL/min per 1.73 m² by 2 weeks after birth, concomitant with alterations in renal blood flow. GFR improves steadily over the first few months of life (Brion et al., 1986) (Table 90.2).

An alternative to SCr is the measurement of serum cystatin C levels. Cystatin C is a low-molecular-weight protein that is freely filtered in the glomerulus and not resorbed. Cystatin C is a member of the cystatin superfamily of cysteine protease inhibitors, and is made by all nucleated cells within the body at a relatively constant rate. Cystatin C does not cross the placental barrier and, as a result of this, does not reflect maternal values. Serum cystatin C remains a functional biomarker that has shown promise in neonates but warrants further study. As a functional biomarker serum, cystatin C has been shown to provide more accurate assessments of neonatal renal function than SCr. Studies evaluating the potential role of cystatin C in neonates have been recently extensively reviewed (Filler and Lepage, 2013).

As mentioned previously, SCr, UOP, and cystatin C are markers of kidney function, not damage. Over the last decade, there has been a significant amount of work to identify urine and serum biomarkers of AKI. Such biomarkers include urine and serum neutrophil gelatinase-associated lipocalin (NGAL), urine interleukin-18, kidney injury marker-1, and liver fatty acid-binding protein, originally identified and studied in neonates undergoing cardiopulmonary bypass (Mishra et al., 2005; Parikh et al., 2006) (Fig. 90.2). These markers will ideally show acute damage hours after an insult, distinguish between different causes and locations of tissue injury, and prognosticate clinical outcomes.

In neonates, it is important to note these urine biomarkers will vary based on gestational age (GA), day of life, and gender (Saeidi et al., 2015). Urine biomarkers of AKI have been tested and show promise in the ability to predict AKI in very low birth weight (VLBW) (Askenazi et al., 2011) and near-term/term neonates (Tanigasalam et al., 2016). Future work is needed before these biomarkers can be used at the bedside. Once we can reliably identify AKI early in the disease process, preventive/therapeutic interventions can be studied to improve outcomes in neonates with AKI.

TABLE 90.1 Definition of Neonatal Acute Kidney Injury

| Stage | Serum Creatinine | Urine Output/24 Hours |
|-------|---|------------------------------|
| 0 | No change in serum creatinine or rise <0.3 mg/dL | >1 mL/kg per hour |
| 1 | SCr rise ≥0.3 mg/dL rise from baseline or SCr rise ≥1.5–1.9 mg/dL × baseline SCr ^a | >0.5 and ≤1 mL/kg per hour |
| 2 | SCr rise ≥2.0–2.9 mg/dL × baseline SCr ^a | >0.3 and ≤0.5 mL/kg per hour |
| 3 | SCr rise ≥3 × baseline SCr ^a or SCr ≥2.5 mg/dL ^a or Receipt of dialysis | ≤0.3 mL/kg per hour |

^aBaseline SCr = lowest SCr prior to measurement.
SCr, Serum creatinine.

TABLE 90.2 Insulin Clearance Glomerular Filtration Rate in Healthy Premature Infants

| Age | mL/min per 1.73 m ² |
|--------------|------------------------------------|
| 1–3 days | 14.0 ± 5.0 (Brion et al., 1986) |
| 1–7 days | 18.7 ± 5.5 (Guignard et al., 1975) |
| 4–8 days | 44.3 ± 9.3 (Barnett et al., 1948) |
| 3–13 days | 47.8 ± 10.7 (Barnett et al., 1948) |
| 1.5–4 months | 67.4 ± 16.6 (Barnett et al., 1948) |
| 8 years | 103 ± 12 (Vanpee et al., 1992) |

• **Fig. 90.2** Mean values of urine interleukin-18 (pg/mL) and neutrophil gelatinase-associated lipocalin (ng/mL) over the first hours after cardiopulmonary bypass in infants who develop acute kidney injury (50% increase in serum creatinine) compared with those who did not develop acute kidney injury. *AKI*, Acute kidney injury; *IL-18*, interleukin-18; *NGAL*, neutrophil gelatinase-associated lipocalin.

Epidemiology

Critically ill neonates experience multiple risks for the development of AKI during their hospitalization, including infections, nephrotoxic medications, and hypotension. The exact incidence of neonatal AKI is difficult to quantify because infants commonly have nonoliguric renal failure and may therefore may not be screened with SCr for AKI. Utilizing legacy definitions of AKI, such as SCr greater than 1.5 mg/dL or initiation of renal replacement therapy (RRT), previous studies had estimated the incidence of neonatal AKI to be 8%–24% with associated mortality rates between 10%–61% (Andreoli, 2004). Over the past decade there has been a significant amount of research utilizing modern staged definitions of AKI to evaluate the incidence and impact of AKI in a number of high-risk patient populations, including neonates with perinatal asphyxia or necrotizing enterocolitis (NEC), those undergoing cardiac surgery or receiving extracorporeal membrane oxygen (ECMO), sick term/premature infants, low birth weight babies, and general neonatal populations (Table 90.3).

Infants With Perinatal Asphyxia

Infants with perinatal asphyxia represent a population known to be at high risk for the development of AKI. Recently there have been several single-center studies evaluating the incidence of AKI, utilizing modern AKI definitions in neonates with perinatal asphyxia. Selewski et al. (2013) evaluated 96 newborns undergoing therapeutic hypothermia for perinatal asphyxia and found that 38% had AKI. In this cohort, AKI was associated with adverse outcomes, with

TABLE 90.3 Neonatal Acute Kidney Injury Studies

| Study | Population | Definition | Incidence of AKI | Findings |
|-----------------------|---|----------------------------------|----------------------------|--|
| Askenazi et al. 2009 | Very low birth weight infants (<i>n</i> = 195) | AKIN criteria | Matched case–control study | AKI is associated with increased mortality after adjustment for confounders. |
| Gadepalli et al. 2011 | Congenital diaphragmatic hernia on extracorporeal membrane oxygenation (<i>n</i> = 68) | RIFLE criteria | 71% | Increased risk of mortality at highest level of AKI (failure) |
| Kaur et al. 2011 | Perinatal asphyxia (<i>n</i> = 36) | AKIN criteria | 41.7% | Modern staging systems (AKIN) capture AKI previously missed by previous standard of SCr >1.5 mg/dl. |
| Koralkar et al. 2011 | Very low birth weight infants (<i>n</i> = 229) | Neonatal modified KDIGO criteria | 18% | Adjusting for severity of illness AKI was associated with increased mortality. |
| Askenazi et al. 2013 | Sick near-term neonates (<i>n</i> = 58) | Neonatal modified KDIGO criteria | 15.6% | AKI associated with increased mortality and positive fluid balance |
| Alabbas et al. 2013 | Cardiac surgery <28 days (<i>n</i> = 122) | AKIN criteria | 62% | Severe AKI (stage III) was associated with increased mortality and length of stay after adjusting for severity of illness. |
| Selewski et al. 2013 | Perinatal asphyxia (<i>n</i> = 96) | Neonatal modified KDIGO criteria | 38% | AKI predicted prolonged mechanical ventilation, length of stay, and abnormal brain MRI findings at 7–10 days of life. |
| Zwiers et al. 2013 | Extracorporeal membrane oxygenation <28 days (<i>n</i> = 242) | RIFLE criteria | 64% | Increased risk of mortality at highest level of AKI (failure) |
| Rhone et al. 2013 | Very low birth weight infants (<i>n</i> = 107) | Neonatal modified KDIGO criteria | 26.2% | AKI is associated with nephrotoxic medication exposure. |

prolonged mechanical ventilation by a mean of 4 days ($P < .001$) and prolonged hospitalization by 3.4 days ($P < .03$). In the same cohort, those with AKI were more likely to have abnormal brain magnetic resonance imaging (MRI) findings at 7 to 10 days of life, implicating AKI as a potential marker and/or mediator of poor neurologic outcomes in infants with perinatal asphyxia (Sarkar et al., 2014). Recently, in a randomized controlled trial of 120 term neonates with perinatal asphyxia, those randomized to therapeutic hypothermia had lower rates of AKI compared with those who received standard care only (32% vs 60%, $P < .05$), suggesting therapeutic hypothermia may protect against the development of AKI (Tanigassalam et al., 2016).

Infants Undergoing Cardiac Pulmonary Bypass Surgery

Several factors contribute to the risk of postoperative AKI in neonates undergoing cardiac pulmonary bypass (CPB) surgery, including prematurity, cardiopulmonary bypass characteristics and duration, surgical complexity, perioperative morbidities, hypotension, deep hypothermic circulatory arrest, and hypoxia (Blinder et al., 2011). The renal outcomes associated with cardiac surgery in pediatric patients have been well studied, and the association of AKI with adverse outcomes is clear. Alabbas et al. (2013) reported an incidence of AKI in 62% of 122 neonates (<28 days) following CPB. Stage 3 AKI was associated with increased mortality and prolonged length of stay. In a multicenter cohort of 264 babies younger than or 6 weeks of age undergoing CPB, Morgan et al. (2013) reported an incidence of AKI of 64%; those with AKI had longer duration of intubation and length of stay, after adjusting for covariates. In a study of 430 infants (≤ 90 days old) Blinder et al. (2011) reported an incidence of CPB-AKI of 52%. After correcting for severity of illness, AKI stage II and III were associated with increased hospital mortality (stage II odds ratio [OR] 5.1, 95% confidence interval [CI] 1.7–15.2; $P = .004$; stage III OR 9.46, 95% CI 2.9–30.7; $P = .0002$).

Infants Requiring Extracorporeal Membrane Oxygenation

Neonates on ECMO are predisposed to AKI for a number of reasons, including those inherent to their underlying critical illness (sepsis, ischemia, respiratory failure, cardiac failure, hypotension, nephrotoxic medications) and elements associated with ECMO (hemodynamic fluctuations, hemolysis, systemic inflammation). Several early studies of infants and children (Sell et al., 1987; Weber et al., 1990; Meyer et al., 2001; Cavagnaro et al., 2007; Shaheen et al., 2007) who receive ECMO suggest both AKI and RRT are associated with mortality. In a retrospective cohort study of 7941 neonates in the extracorporeal life support organization registry, where AKI was defined as infants in the registry who had an SCr greater than 1.5 mg/dL or an ICD-9 code for acute renal failure, neonatal mortality was 2175/7941 (27.4%). Nonsurvivors experienced more AKI than survivors (413/2175 [19.0%] vs 225/5766 [3.9%]; $P < .0001$), and more received RRT (863/2175 [39.7%] vs. 923/5766 [16.0%]; $P < .0001$). After adjusting for confounding variables, the adjusted OR for mortality was 3.2 ($P < .0001$) following AKI and 1.9 ($P < .0001$) for those given RRT. Zwiers et al. (2013) evaluated AKI in 242 neonates on ECMO, reporting an AKI incidence of 64% and a mortality of 65% when AKI progressed to the highest stage. These findings are similar to those reported by Gadepalli et al. (2011) in their evaluation of 68 neonates with congenital diaphragmatic hernia on ECMO, where AKI occurred in 71% of neonates, and those with the highest stage of AKI had a significantly increased mortality of 73%.

Very Low Birth Weight and Extremely Low Birth Weight Neonates

There are now several single-center studies describing the epidemiology of AKI in premature infants. Askenazi et al. performed a case-control study matching premature infants by GA and birthweight and found that for every 1 mg/dL increase in SCr, the odds of death doubled (OR 1.94, 95% CI 1.13–3.32). The odds of death increased when confounding variables were adjusted (adjusted OR 3.44, 95% CI 1.23–9.61). In 2011, Koralkar et al. (2011) reported an 18% incidence of AKI in 229 VLBW infants and showed that infants with AKI had significantly higher mortality than those without AKI (42% vs 5%; $P < .001$), which persisted after adjusting for confounding variables (hazard ratio [HR] 2.4, 95% CI 0.95–6.00; $P = .06$). Viswanathan et al. (2012) reported an incidence of AKI of 12.5% in 472 extremely low birth weight (ELBW) infants in a single-center retrospective study. In this case-control study, those with AKI had significantly increased mortality (70% vs 22%; $P < .001$). Carmody et al. (2014) reported a higher incidence of AKI of 39.8% in a retrospective study of 455 VLBW infants. In this study, AKI was independently associated with increased mortality (OR 4.0, 95% CI 1.4–11.5) and length of stay (11.7 hospital days, 95% CI 5.1–18.4). Large prospective multicenter cohort studies with contemporary definitions of AKI are currently under way.

One of the most common morbidities of prematurity is bronchopulmonary dysplasia (BPD), affecting 10% and 40% of surviving VLBW and ELBW infants, respectively (Eichenwald and Stark, 2008). The pathophysiology of this chronic lung condition involves elevated levels of proinflammatory interleukins, tumor necrosis factor- α (TNF- α), leukotrienes, and increased pulmonary vasculature permeability, which culminate in abnormal lung development and fibrosis. Not only does AKI cause pulmonary edema secondary to volume overload, but evidence in ischemic, nephrotoxic, and bilaterally nephrectomized animal models shows that AKI induces a proinflammatory process highlighted by increased levels of neutrophils, TNF- α , interleukins, free radicals, endothelial growth factors, and granulocyte colony-stimulating factor (G-CSF) (Kim et al., 2006; Hoke et al., 2007; Faubel, 2008). In 2015, Askenazi et al. showed an association between AKI and BPD in premature infants. Those with AKI had a 70% higher risk of oxygen requirement/death at 28 days old (risk ratio [RR] 1.71, 95% CI 1.22–2.39; $P < .002$). This association remained after controlling for GA, preeclampsia, 5-minute Apgar score, and maximum percentage weight change in the first 4 days (RR 1.45, 95% CI 1.07–1.97; $P < .02$). Those without AKI were 2.5 times more likely to come off oxygen (HR 1.3–5.0; $P < .02$) than those with AKI, even when controlling for GA, preeclampsia, 5-minute Apgar, and maximum percentage weight change (multivariate HR 2.0, 95% CI 0.9–4.0; $P < .06$) (Askenazi et al., 2015).

Pathophysiology of Neonatal Acute Kidney Injury

Prerenal

Prerenal azotemia occurs in response to decreased renal blood flow (RBF). Causes of prerenal azotemia in neonates include loss of effective circulating blood volume (perinatal blood loss, hemorrhage), dehydration (diarrhea, transepidermal free water losses, poor intake, gastric or chest tube losses), capillary leak (hydrops, infection, or hypoalbuminemia), increased abdominal pressures (NEC, repair or reduction of gastroschisis, omphalocele,

TABLE 90.4 Causes of Acute Kidney Injury in the Newborn

| Prenatal Azotemia | Intrinsic Acute Kidney Injury | Obstructive Renal Failure |
|---------------------------------|-------------------------------|---------------------------|
| Loss of effective blood volume | Acute tubular necrosis | Congenital malformations |
| Absolute loss | Severe renal ischemia | Imperforate prepuce |
| Hemorrhage | Nephrotoxins | Urethral stricture |
| Dehydration | Infections | PUV |
| Relative loss: ↑ capillary leak | Congenital infections | Urethral diverticulum |
| Sepsis | Pyelonephritis | Ureterocele |
| NEC | Bacterial endocarditis | Megaureter |
| RDS | Renal vascular causes | UPJ obstruction |
| ECMO | Renal artery thrombosis | Extrinsic compression |
| Hypoalbuminemia | Renal vein thrombosis | Sacroccygeal teratoma |
| Renal hypoperfusion | DIC | Hematocolpos |
| Congestive heart failure | Nephrotoxins | Intrinsic obstruction |
| Pharmacologic agents | Aminoglycosides | Renal calculi |
| Indomethacin | Indomethacin | Fungus balls |
| Tolazoline | Amphotericin B | Neurogenic bladder |
| ACE inhibitors | Radiocontrast dyes | |

congenital diaphragmatic hernia, ascites), and decreased cardiac output (cardiac surgery, heart failure, or use of ECMO), which results in a lack of pulsatile flow (Liem et al., 1995). Nonsteroidal antiinflammatory drugs (NSAIDs) such as indomethacin and angiotensin-converting enzyme inhibitors (ACE-Is) can also decrease RBF (Table 90.4).

When low RBF occurs, renal autoregulation preserves GFR by increasing renal sympathetic tone, activation of the renin-angiotensin-aldosterone system, and increased activation of hormones such as vasopressin and endothelin. Increase in filtration fraction ($GFR/RBF \times 100$) increases peritubular oncotic pressure, resulting in enhanced proximal tubular sodium and water reabsorption (Feld et al., 1986) in those with intact tubular function. These renal hemodynamic changes lead to a decrease in water and sodium losses, to maintain systemic volume expansion and blood pressure. In some newborns, oliguria does not develop because of poor vasopressin secretion, weak renal responsiveness to vasopressin (Dixon and Anderson, 1985), poor tubular function in underdeveloped tubular cells, or prolonged/severe hypoperfusion. In the context of renal hypoperfusion, correction of the underlying condition restores normal renal function unless renal hypoperfusion has been so severe or prolonged that renal parenchymal damage has already developed. Once parenchymal damage occurs, renal tubular cell damage (acute tubular necrosis) occurs even if renal perfusion is restored.

Intrinsic Acute Kidney Injury

Prolonged or severe hypoperfusion is the most common cause of intrinsic AKI. Other causes of intrinsic AKI include nephrotoxic

medications and sepsis, which can cause AKI with either hypodynamic or hyperdynamic blood flow. Other rare causes of AKI include renal vein thrombosis, renal artery thrombosis, uric acid nephropathy, hemoglobinuria, and myoglobinuria (Table 90.4). Congenital abnormalities of kidneys and urinary tract are discussed further in the section under chronic kidney disease (CKD) of the newborn.

Ischemic Acute Kidney Injury

The presentation and course of the renal damage after hypoxic ischemic injury depends on the severity and duration of the insult. In contrast to prerenal azotemia, renal function abnormalities in intrinsic AKI are not immediately reversible. The severity of intrinsic AKI ranges from mild tubular dysfunction, to acute tubular necrosis, to renal infarction and corticomedullary necrosis with irreversible renal damage (Feld et al., 1986).

Prerenal azotemia and ischemic AKI are a continuum of physiologic responses. The main difference between prerenal AKI and ischemic AKI is that in the latter, hypoperfusion induces renal parenchymal cell injury, particularly to the tubular epithelium of the terminal medullary portion of the proximal tubule (S3 segment) and of the medullary portion of the thick ascending limb of the loop of Henle.

The course of ischemic AKI may be subdivided into the prerenal, initiation, extension, maintenance, and recovery phases (Sutton et al., 2002) (Fig. 90.3). If, during prerenal azotemia, restoration of RBF occurs, GFR can return promptly to normal. The initiation phase includes the original insult and the associated events resulting in a drop in GFR. Tubular dysfunction with low GFR represents

• **Fig. 90.3** Schematic representation of stages of the progression in acute kidney injury. *GFR*, Glomerular filtration rate.

the maintenance phase. The duration of the maintenance phase depends, at least in part, on the severity and duration of the initial insult. The recovery phase is characterized by the gradual restoration of *GFR* and tubular functions, which can take months to occur. During the maintenance and recovery phase of AKI, the kidney is susceptible to further damage from additional insults. Recognition of the different phases of intrinsic AKI is helpful in the diagnosis, clinical management, and prognostication of the disorder.

The histologic hallmark of severe ischemic AKI is damage to epithelial tubular cells with characteristic bleb formation and loss of brush border in the apical portion of the cell cytoskeleton disruption and loss of tight junctions between cells. If injury is severe enough, apoptosis and necrosis will occur with resultant desquamation of cells, which lead to tubular obstruction. Not only are tubular epithelial cells critical in the pathophysiology of ischemic AKI, but damage to the innermost lining of the renal vascular system, the endothelial cells, has a critical role in the initiation, extension, maintenance, and recovery phases of ischemic AKI (Basile, 2007).

When endothelial cell damage occurs, activation of vasoconstriction, impaired vasodilation, and impaired leukocyte adhesion result in capillary obstruction and distorted peritubular capillary morphology. Capillary obstruction and impaired morphology lead to a cycle of increasing ischemia and vascular inflammation. The loss of endothelial cell function may represent an important therapeutic target in which vascular support and/or endothelial regeneration by progenitor cell may impact the short- and long-term consequences of AKI (Liu and Brakeman, 2008).

Damaged endothelial and tubular cells not only lead to dysfunction within the kidney, but they produce a systemic inflammatory response, which leads to significant distant organ dysfunction. The inflammatory dysregulation is due (at least in part) to dysfunctional immune, inflammatory, and soluble mediator metabolism. AKI also has been shown to directly affect brain, lung, heart, liver, bone marrow, and gastrointestinal tract (Awad and Okusa, 2007). Mice with AKI (induced by bilateral renal ischemia for 60 minutes) had increased levels of the proinflammatory chemokines keratinocyte-derived chemoattractant and G-CSF in the cerebral cortex and hippocampus, which resulted in increased neuronal pyknosis and microgliosis in the brain (Liu et al., 2008; Liu and Brakeman, 2008). In the lung, mechanistic studies demonstrate that AKI induces increased pulmonary vascular permeability, soluble and cellular inflammation, and dysregulated salt and water channels.

TABLE 90.5 Nephrotoxic Medications

| Drug | Mechanism |
|--|--|
| Acyclovir | Urinary precipitation, especially with low flow and hypovolemia, with renal tubular obstruction and damage and decreased <i>GFR</i> . May cause direct tubular toxicity (metabolites) |
| Angiotensin-converting enzyme inhibitors | Decreased angiotensin II production inhibiting compensatory constriction of the efferent arteriole to maintain <i>GFR</i> |
| Aminoglycosides | Toxic to the proximal tubules (transport in the tubule, accumulate in lysosome, intracellular rise in reactive oxygen species and phospholipidosis, cell death); intrarenal vasoconstriction and local glomerular/mesangial cell contraction |
| Amphotericin B | Distal tubular toxicity, vasoconstriction, and decreased <i>GFR</i> |
| Nonsteroidal antiinflammatory drugs | Decreased afferent arteriole dilatation as a result of inhibiting prostaglandin production resulting in reduced <i>GFR</i> |
| Radiocontrast agents | Renal tubular toxicity secondary to increase in reactive oxygen species; intrarenal vasoconstriction may play a role |
| Vancomycin | Mechanism of AKI unclear, possible mechanism includes proximal tubular injury with generation of reactive oxygen species |

AKI, Acute kidney injury; *GFR*, glomerular filtration rate.

Because neurologic and pulmonary morbidity are very high in the critically ill neonatal population, the potential deleterious effects of AKI on these organs need to be explored.

In many cases, a combination of several causative factors contributes to the development of acute renal failure. For instance, absolute hypovolemia, increased capillary leak-induced loss of effective circulating blood volume, and reflex renal vasoconstriction all may contribute to renal hypoperfusion and ensuing renal injury in newborns with severe forms of shock.

Nephrotoxic Acute Kidney Injury

Exposure to nephrotoxic medications is a potentially modifiable risk factor for intrinsic AKI in critically ill children and neonates. Table 90.5 lists commonly used nephrotoxic medications in the neonatal intensive care unit (NICU) and their mechanism of nephrotoxicity. Until recently the epidemiology and burden of nephrotoxic medication exposure in neonates were unknown. Rhone et al. (2014) recently evaluated the cumulative nephrotoxic medication exposure of a cohort of 107 VLBW neonates. In this study, 87% of the cohort was exposed to at least one nephrotoxic medication, and on average these neonates were exposed to over 14 days of nephrotoxic medications. In a number of pediatric patient populations, nephrotoxin-associated AKI has been linked to adverse outcomes including increased length of stay and cost (Zappitelli et al., 2011).

In the NICU, nephrotoxins can cause AKI by decreasing renal perfusion (NSAIDs, diuretics, ACE-Is), direct tubular injury (aminoglycosides, cephalosporins, amphotericin B, rifampin, vancomycin, NSAIDs, contrast media, myoglobin/hemoglobin [Hgb]), interstitial nephritis, and tubular obstruction (acyclovir). Although not a comprehensive review, some of the most common nephrotoxic medications in neonates are described.

Indomethacin, a prostaglandin inhibitor used to treat patent ductus arteriosus in premature infants, is one of the most commonly used medications in the NICU. Severe, although usually transient, nephrotoxicity can occur with indomethacin administration. The potentiation of the vasoconstrictive and sodium- and water-retaining effects of angiotensin II, norepinephrine, and vasopressin by the indomethacin-induced inhibition of renal prostaglandin production is the primary mechanism of the renal actions of the drug. Because neonatal renal function is more dependent on local prostaglandin production (especially when intravascular volume is decreased as a result of fluid restriction, increased capillary leak, and transepidermal water losses in the preterm infant with patent ductus arteriosus), indomethacin administration is commonly associated with elevated SCr concentrations, decreased urine output, and hyponatremia (Cifuentes et al., 1979).

Amphotericin B alters renal function by directly affecting tubular function, resulting in renal tubular acidosis and increased urinary potassium excretion. Although these nephrotoxic effects are most often reversible, cases of fatal neonatal renal failure caused by amphotericin B toxicity have been reported (Baley et al., 1984). Amphotericin B lipid complex (ABLC), liposomal amphotericin, and other lipid formulations of this drug consist of nonliposomal lipid bilayers complexed with amphotericin B. This lipid bilayer results in a higher affinity to fungal rather than mammalian cellular membranes and therefore is less nephrotoxic (Wurthwein et al., 2005). Auron et al. (2007) recently showed no differences in blood urea nitrogen or SCr, serum sodium, or serum potassium in 35 premature infants (average birthweight 764 ± 196 g) treated with ABLC compared with similar infants (controlling for GA and birthweight). Thus a 2-week course of ABLC is likely safe in premature infants, although studies to explore longer-term use of ABLC are needed.

Aminoglycosides are one of the most commonly used medications used in the treatment of suspected or proven neonatal sepsis. Aminoglycosides inhibit lysosomal phospholipases, leading to primary proximal tubule cell damage (Giuliano et al., 1984), although changes in the ultrastructure of the glomerulus also occur (Ojala et al., 2001). A metaanalysis of 11 studies in septic neonates showed that both once-a-day and multiple-dose regimens showed adequate clearance of sepsis. Even though rates of ototoxicity or nephrotoxicity were not different among the two groups, pharmacokinetic studies revealed that once-a-day dosing caused less drug accumulation in the kidney's proximal cells and more commonly achieved adequate peak concentrations (>5.0 mcg/dL) while avoiding toxic trough levels (<2 mcg/dL) (Rao et al., 2006).

Aminoglycosides should be used with caution in any person with renal dysfunction, concomitant nephrotoxic medication use or poor renal perfusion (due to volume, hypoalbuminuria, heart failure). In those with renal dysfunction, serial monitoring to assure proper clearance of the medication is needed to prevent AKI. Because aminoglycoside toxicity is usually nonoliguric, serial monitoring of SCr values is necessary, especially during prolonged administration of these antibiotics, to detect their potential nephrotoxicity in the newborn.

Acyclovir has replaced vidarabine for treatment of infection with herpes simplex virus (HSV) because of its ease of use and

more favorable side effect profile. High-dose acyclovir (60 mg/kg per day for 21 days) decreased the mortality of neonatal HSV sepsis and central nervous system disease to 29% and 4%, respectively (Kimberlin et al., 2001). Acyclovir is an antiviral agent that is eliminated rapidly in the urine through glomerular filtration and tubular secretion. It is nearly insoluble in the urine and may precipitate, particularly in the distal tubular lumen. Intravenous high-dose acyclovir treatment may lead to intratubular crystal precipitation and renal failure. Acyclovir-related nephrotoxicity can be limited by avoiding its use in those with renal insufficiency or intravascular volume depletion, infusing the drug slowly (over several hours), and by assuring adequate hydration to maintain high urinary flow rate, which will reduce the likelihood of crystal deposition in the tubules (Izzedine et al., 2005).

Finally, medications given to pregnant women may cause combined ischemic and nephrotoxic renal injury in the fetus, resulting in the clinical presentation of AKI after birth. A frequently used class of medications that falls into this category is the NSAIDs prescribed for tocolysis—both nonselective and selective cyclooxygenase inhibitors such as indomethacin or ketoprofen (Bannwarth et al., 1999; Peruzzi et al., 1999), which can lead to severe AKI in the newborn.

Postrenal Acute Kidney Injury

The most common causes of obstructive kidney dysfunction in the newborn are congenital malformations, including imperforate prepuce, urethral stricture, prune belly syndrome, and posterior urethral valves. Other causes of acute obstruction include neurogenic bladder, extrinsic compression (e.g., hematocolpos, sacrococcygeal teratoma), and intrinsic obstruction from renal calculi or fungal balls. Depending on the cause and associated damage to the kidneys, relief of the obstruction will markedly improve renal function.

Evaluation and Management of Neonatal Acute Kidney Injury

There are three main goals in the care of neonates with AKI. First is to understand the cause of the problem. Second is to take steps to intervene to prevent further deterioration in kidney function. Third is to provide renal support to the patient by helping achieve proper homeostasis and blood pressure control, provide the synthetic substance that the failed kidney lacks, and assist in toxic clearance. Similar steps parallel proper care for the newborn with CKD.

Step 1: Understand the Cause of Acute Kidney Injury

The pregnancy history, findings on prenatal tests, vital signs, changes in weight, physical examination, interventions, and medications prescribed provide important clues about the cause of neonatal AKI. SCr often does not rise for days after an injury, thus monitoring these values for several days after the inciting event is necessary to determine if AKI occurred. If urine is available, a urinalysis, urine culture, and a spot urine sample for sodium, creatinine, and osmolality can help differentiate the cause. Serum laboratory values can help understand the cause of AKI and should be monitored sequentially. These include serum sodium, potassium, chloride, bicarbonate, calcium, phosphorus, magnesium, urea, creatinine, uric acid, glucose, blood gases, Hgb, and platelets.

One of the major goals in the initial evaluation of neonatal AKI is to determine if the kidney is hypoperfused. Several laboratory, clinical, and therapeutic interventions can help delineate prerenal azotemia from intrinsic AKI (Table 90.6). Decrease in body weight, tachycardia, dry mucous membranes, poor skin turgor, flattened

TABLE 90.6 Diagnostic Indices Suggestive of Prerenal Azotemia Versus Intrinsic Acute Kidney Injury in the Newborn

| | Prerenal Azotemia | Intrinsic Acute Kidney Injury |
|------------------------------------|---------------------------------------|------------------------------------|
| Urine flow rate (mL/kg per hour) | Variable | Variable |
| Urine osmolality (mOsm/L) | >400 | ≤400 |
| Urine-to-plasma osmolar ratio | >1.3 | ≤1.0 |
| Urine-to-plasma creatinine ratio | 29.2 ± 1.6 ^c | 9.7 ± 3.6 ^c |
| Urine [Na ⁺] (mEq/L) | 10–50 | 30–90 |
| FENa ^a (%) | <0.3 (0.9 ± 0.6) ^c | >3.0 (4.3 ± 2.2) ^c |
| Renal failure index ^{a,b} | <3.0 (1.3 ± 0.8) ^c | >3.0 (11.6 ± 9.5) ^c |
| Response to fluid challenge | Improved tachycardia Increased UOP | No effect on tachycardia or UOP |

^aFractional excretion of sodium (FENa) = (urine [Na⁺]/serum [Na⁺])/(urine [Cr]/serum [Cr]) × 100.

^bRenal failure index = urine [Na⁺]/(urine [Cr]/serum [Cr]).

^cMean ± standard deviation.

UOP, Urine output.

Data from Feld et al., 1986; Karłowicz and Adelman, 1992; and Mathew et al., 1980. See text for details.

anterior fontanel, and elevation of serum sodium can be seen in those with low intravascular volumes.

When the kidney is hypoperfused, the kidney will avidly retain sodium and water to preserve overall intravascular volume. Laboratory markers of prerenal azotemia include low urinary sodium excretion, low fractional excretion of sodium (FENa), low renal failure index, and high blood urea nitrogen:SCr ratio. However, it is important to recognize that preservation of urine sodium and water is dependent on intact tubular function; therefore disturbances of tubular function (from diuretic use, tubular injury, or primary tubular diseases) can affect the tests. As premature infants have poor tubular function, these studies have important limitations. Normal FENa in preterm infants born at less than 32 weeks of gestation is usually higher than 3% (Ellis and Arnold, 1982). Additionally, because of the developmentally regulated limitation of their concentrating capacity and the effects of low protein intake and urea excretion on urine osmolality, the urine-to-plasma creatinine ratio instead of the urine-to-plasma osmolar ratio should be used in newborns to evaluate their renal tubular reabsorptive capacity (Feld et al., 1986).

If the suspicion of renal hypoperfusion is high, an appropriate fluid challenge with 10–20 mL/kg of isotonic fluids (usually normal saline) over 30 minutes should be given. Close observation of vital signs and UOP may serve to delineate if intravascular hypoperfusion is present. Several boluses may be necessary with careful prescription of fluid volume for the next 24 hours. Care to avoid fluid challenges is advised in those with suspected urinary outlet obstruction, lung pathology such as BPD, or congestive heart failure.

Another important part of the evaluation of AKI is to assure that there is no obstruction to urine flow. A renal and bladder

ultrasound should be performed without delay if an obstructive process is suspected and to determine if congenital renal abnormalities are present. If hematuria or hypertension (or both) are present, the possibility of renal vascular disease should also be considered. Doppler ultrasound of the renal vessels can be performed if renal vascular thrombosis is suspected.

Step 2: Intervene to Preserve or Prevent Further Acute Kidney Injury

The approach using provision of fluid boluses (if appropriate) as part of the evaluation of prerenal azotemia also serves as the initial management of AKI. Careful evaluation of any potentially nephrotoxic medications to determine if they are necessary, and/or if alternatives are available, is crucial. Clearly the clinician can reverse or prevent further damage by maintaining adequate renal perfusion, relieving abdominal compartment syndrome if present, assuring adequate oncotic pressure (keeping a serum albumin of 2.5 mg/dL or higher) and, if obstruction of the urinary outflow is discovered, provide interventions to eliminate the obstruction. If systemic hypotension develops despite adequate volume administration, early initiation of blood pressure support often establishes appropriate renal perfusion (Seri et al., 1993; Seri et al., 1998). In cases of pressor/inotrope-resistant hypotension and shock, a brief course of low-dose hydrocortisone can be effective in restoring systemic perfusion and renal function in preterm neonates (Seri, 2001). Other management goals include the maintenance of blood oxygen content, provision of blood products for specific indexes, limiting severe acidosis, and maintenance of normal serum albuminemia (at least 2.5 mg/dL preferably). If abdominal compartment syndrome is noted, the kidney will need higher blood pressure or relief of abdominal pressure with a drain to maintain perfusion.

Several therapies are commonly employed in AKI; however, little, if any, data are available to support the use of low-dose dopamine, fenoldopam (a selective dopamine-1 receptor agonist), or diuretics for the treatment or prevention of AKI.

Low-dose dopamine can increase renal perfusion in the sick preterm and term infant with prerenal azotemia caused by hypoxemia, acidosis, or indomethacin administration (Seri, 1995; Seri et al., 1998; Seri et al., 2002). Although low-dose dopamine increases renal perfusion, well-powered randomized controlled studies (Bellomo et al., 2000) and several metaanalyses in adults with AKI have come to the same conclusion: compared with placebo, low-dose dopamine does not improve survival, shorten hospital stay, or limit dialysis use (Marik, 2002; Friedrich et al., 2005; Hoste et al., 2006). Similar studies have not been performed in children or neonates.

Fenoldopam is a selective dopamine-1-receptor agonist the effects of which include vasodilation of renal and splanchnic vasculature, increased RBF, and increased GFR. It is approved in adults for treatment of severe hypertension but is not approved for the treatment of AKI. Nonetheless, its use in neonates with AKI has been explored in several single-center analyses, with conflicting results. Two retrospective single-center analyses (Moffett et al., 2008; Yoder and Yoder, 2009) found increased urine output in a select group of neonates with oliguria. In contrast, in a prospective placebo-controlled trial of low-dose fenoldopam (0.1 mcg/kg per min) in infants undergoing cardiac surgery with cardiopulmonary bypass (Ricci et al., 2008), low-dose fenoldopam did not show beneficial effects on AKI incidence, fluid balance control, time to sternal closure, time to extubation, or time to intensive care discharge.

Diuretics are commonly used to induce diuresis in critically ill neonates; however, no studies in neonates, children, or adults have

shown that diuretics are effective in preventing AKI or improving outcomes once AKI occurs (Bellomo et al., 2000). The mannitol test (used to test if a patient has renal hypoperfusion) is contraindicated in newborns with a predisposition to the development of intraventricular hemorrhage or periventricular leukomalacia, because of the drug-induced sudden increase in serum osmolality.

Step 3: Provide Renal Support

The clinician has an important role in helping to achieve homeostasis, and careful attention to what fluid/electrolytes are being delivered to the patient is critical. Managing fluids in the critically ill neonate with AKI can be very difficult. These infants may require large volumes of fluid to maintain adequate nutrition and hematologic indices and to provide appropriate medications. However, in an oliguric/anuric child these fluids can be detrimental as they can cause congestive heart failure, chest wall edema, and pulmonary failure. Therefore once adequate intravascular volume has been restored, prevention of severe fluid overload (by limiting crystalloid infusions) and the maximization of nutritional supplement concentration should be undertaken. Severe fluid restriction, limiting intake to insensible, gastrointestinal, and renal losses, is sometimes required but is performed at the heavy price of inadequate nutrition. Decisions on placement of dialysis access should be considered early in the course of AKI before severe fluid overload has occurred, because once severe fluid overload occurs, placement of a peritoneal dialysis (PD) or a hemodialysis (HD) catheter can be significantly more difficult, as is support of the infant with severe pulmonary edema.

Although diuretics do not impact the course of AKI, they can be used to assist in maintaining fluid homeostasis. If an adequate dose of a loop diuretic (i.e., 1 mg/kg of furosemide intravenously) does not improve UOP, it is unlikely that higher doses, changing diuretic, and/or changing to continuous dose will benefit the infant, and their use could have important side effects. In cardiac surgery patients, continuous doses were shown to be as effective with smaller total quantities of medication required and may provide less risk for nephrotoxicity or ototoxicity than larger intermittent dosing (Luciani et al., 1997). The potential toxicity of long-term and aggressive furosemide therapy, including ototoxicity, interstitial nephritis, osteopenia, nephrocalcinosis, hypotension, and persistence of patent ductus arteriosus, should be taken into consideration, especially in the preterm newborn (Karlowicz and Adelman, 1992).

Hypertension is common in neonates with AKI. It can be due to increased renin release in malformed/damaged kidneys or secondary to increased intravascular volume from a lack of free water clearance. If hypertension is due to fluid overload, inducing free water clearance with diuretics or fluid removal with dialysis will address its cause. Calcium-channel blockers work by selectively causing vasodilation of the venous system. Short-acting calcium-channel blockers (isradipine for example) are reliable, have a quick onset of response, and are well-tolerated medications. Long-acting calcium-channel blockers (amlodipine for example) take longer to take effect but provide less lability with longer dosing intervals. β -Blockers (propranolol or labetalol) are also commonly used to treat hypertension in neonates. Use of ACE-Is in children with ischemic AKI should be avoided as they can produce further renal hypoperfusion and alter intrarenal hemodynamics in an already injured kidney. See Chapter 93 for more information on neonatal hypertension.

Electrolyte abnormalities can vary depending on the cause of AKI. For example, aminoglycoside toxicity is commonly nonoliguric

with ongoing potassium and magnesium losses. Alternatively, ischemic AKI causes oliguria/anuria hyponatremia, hyperkalemia, hyperphosphatemia, and hypocalcemia. Polyuria with electrolyte (especially bicarbonate) losses may occur following the relief of a urinary obstruction. Management of electrolyte disorders can usually be managed by attention to electrolyte intake during initial course of AKI, frequent evaluation, and specific therapies.

Most cases of hyponatremia are due to water overload and, less commonly, low total sodium body composition. Attention to fluid status is critical to determine the cause and proper therapy of hyponatremia. In cases of nonsymptomatic hypervolemic hyponatremia (serum sodium concentrations usually between 120 and 130 milliequivalent [mEq]/L), restriction of free water intake is recommended. If hyponatremia at this level results in clinical signs and symptoms (lethargy, seizures) or serum sodium concentration falls below 120 mEq/L, use of 3% sodium chloride over 2 hours according to the following formula should be considered, but caution should be used to assure that the sodium (Na) is not corrected too quickly.

Possible complications of hypertonic saline administration include congestive heart failure, pulmonary edema, hypertension, intraventricular hemorrhage, and periventricular leukomalacia. Care should be taken not to increase serum sodium concentration more rapidly than 0.5 mEq/hour.

Severe hyperkalemia is a life-threatening medical emergency. Signs of progressive hyperkalemia on the electrocardiogram, in order of severity, consist of tall peaked T waves, heart block with widened QRS complexes, U wave formation, the development of sine waves, and finally cardiac arrest. Medications used to manage hyperkalemia, with their dose, onset, and duration of action, are listed in Table 90.7. Measures to remove potassium from the body

TABLE 90.7 Medical Management of Hyperkalemia in the Newborn

| Drug | Dose | Onset of Action | Duration of Action |
|-------------------------------------|---|---------------------|---------------------|
| Calcium gluconate (10%) | 0.5–1 mL/kg (IV over 10 min) | 1–5 min | 15–60 min |
| Sodium bicarbonate (3.75% solution) | 1–2 mEq/kg (IV over 10 min) | 5–10 min | 2–6 hr |
| Insulin | 1 IU/5 g glucose (IV bolus or continuous infusion) | 15–30 min | 4–6 hr |
| Glucose | ≤14 mg/kg per min (IV bolus or continuous infusion) | 15–30 min | 4–6 hr |
| Furosemide | 1 mg/kg dose or as continuous infusion | 5–10 min | 2–3 hr |
| Sodium polystyrene sulfonate | 1 g/kg dose q6h as needed (orally/rectally) | 1–2 hr ^a | 4–6 hr |
| Dialysis | As per nephrology | Immediate | Duration of therapy |

^aOnset of action may take up to 6 hours, and the drug may be ineffective in preterm infants born at less than 29 weeks of gestation. See text for details.

IU, International unit; IV, intravenous.

include oral or rectal sodium polystyrene powder (Kayexalate), loop diuretics to enhance potassium excretion (if not anuric), and dialysis. Several methods to move potassium from the extracellular to the intracellular compartment are available including albuterol inhalation, sodium bicarbonate, and insulin/glucose. Adequate ionized calcium levels for cardioprotection should be sought in context of hyperkalemia. In 2007, Vemgal and Olhson performed a metaanalysis of studies on the management of hyperkalemia in premature infants. Given the limited data available, no firm clinical practice recommendations on which treatment modality was best for the treatment of infants with hyperkalemia were able to be made except that insulin/glucose may be better in premature infants (Vemgal and Ohlsson, 2007).

Hyperphosphatemia is common in AKI and should be treated with low phosphorus intake. Breast milk and Similac 60/40 both contain low phosphorous and low potassium in comparison with other neonatal infant formulas. Significant elevations in serum phosphate represent a risk of development of extraskeletal calcifications of the heart, blood vessels, and kidneys in the newborn, especially when the calcium–phosphorus product exceeds 70 (Sell et al., 1987). Calcium carbonate may be used as a phosphate-binding agent in those whose phosphorous intake exceeds excretion. Although rarely an indication for dialysis without fluid overload or hyperkalemia, severe hyperphosphatemia is best treated with dialysis.

Hypocalcemia is low in neonates with severe and prolonged AKI, especially those who develop an inability to convert 25-hydroxy-vitamin D to 1-25-hydroxy vitamin D. Ionized calcium should be measured in those with low total calcium levels as concurrent hypoalbuminemia can affect total calcium levels. If ionized calcium is decreased and the newborn is symptomatic, 100–200 mg/kg of calcium gluconate should be infused over 10 to 20 minutes and repeated every 4 to 8 hours as necessary. Oral or intravenous calcitriol may be administered to increase intestinal reabsorption of calcium.

Normal acid–base homeostasis depends on the kidneys' ability to reabsorb bicarbonate. Thus infants with AKI commonly have a nonanion gap metabolic acidosis. Replacement with bicarbonate or acetate as a base is indicated in those with AKI to avoid or treat metabolic acidosis. In infants with severe respiratory failure, large doses of bicarbonate should be avoided as this can result in respiratory acidosis with increased carbon dioxide retention.

Nutritional goals in infants with AKI are similar to those of infants without AKI. Commonly, parental nutrition and/or feeds will need to be concentrated to avoid excessive fluid gains. If nutritional goals are unable to be achieved due to oliguria/ongoing fluid overload, the potential risks of dialysis therapy versus the potential risks associated with inadequate caloric and protein needs should be discussed. If a neonate is on continuous peritoneal or HD, an additional 1 g/kg per day of protein is needed to supplement the protein losses that occur with this form of dialysis (Zappitelli et al., 2008, 2009).

In a neonate with AKI, careful assessment of medication dosing is imperative. Because many drugs are excreted in the urine, impaired metabolism or clearance from the kidneys can cause drug accumulation and adverse side effects. In those on dialysis, pharmacokinetic properties (volume of distribution, protein binding, size, charge) of drugs, dialysis modality (peritoneal vs HD), and interval of dialysis (intermittent vs continuous) will affect drug availability (Churchwell and Mueller, 2009). Consultation with pharmacists and nephrologists familiar with drug dosing in renal failure is invaluable for neonates with AKI.

Renal Support Therapy With Dialysis

Renal support therapy, either through the use of the peritoneal membrane or with the extracorporeal blood system, does not prevent or treat AKI or CKD; it is used solely to support the infant who lacks adequate kidney function. The decision to initiate dialysis (especially in those infants with severe congenital malformations of the kidney and urinary tract) is complex and requires a multidisciplinary approach to guide the family as they consider very difficult decisions (see later on decisions to initiate RRT). Access placement and some technical challenges make neonatal dialysis more difficult than in older children, but this therapy is feasible in experienced programs with dedicated pediatric nephrologists, neonatologists, dialysis nurses, and surgeons.

Indications for Dialysis Initiation

Absolute indications to initiate dialysis include severe electrolyte abnormalities that are not correctable with medical interventions, life-threatening intoxications of medications that can be cleared with dialysis, inborn errors of metabolism, fluid overload that leads to pulmonary edema or other organ dysfunction, inability to provide adequate nutritional requirements because of renal compromise, and uremia. If renal dysfunction and/or fluid overload occurs, discussions about dialysis initiation should occur early because prolonged fluid overload/uremia can worsen pulmonary edema and cardiopulmonary instability and make placement of access for dialysis very difficult.

The timing of initiation of dialysis for those with AKI is controversial. Several observational studies show a clear advantage in adults who are dialyzed early versus late (Ronco et al., 1986; Liu et al., 2006), and pediatric studies have begun to show similar findings. The impact of fluid overload on outcomes in critically ill patients has been a hot topic across medicine. Pediatricians have been at the forefront of identifying the degree of fluid overload at the initiation of renal replacement as an independent risk factor for survival in critically ill children (Goldstein et al., 2001; Gillespie et al., 2004; Symons et al., 2007). Further studies evaluating the impact of fluid overload on outcomes in neonates need to be performed. Advocates for early initiation of renal support argue that critically ill patients benefit from early dialysis because they can remove excess fluid sooner, gain metabolic control faster, and provide renal support to allow for provision of maximal nutrition without progressive fluid overload. As technical access and machine advances have made neonatal dialysis safer and technically possible, early initiation of dialysis may improve outcomes in critically ill neonates with AKI. Further studies are needed before recommendations on timing of dialysis can be made.

Access

The limiting factor in performing dialysis in the smallest of babies is access to the peritoneal space or the vascular space for dialysis. The ideal acute PD access is a noncuff or single-cuff coiled catheter specifically designed for neonates undergoing PD. If this is not available, the use of a catheter that is used for chest tube drainage, or other catheters that may be available, can be lifesaving. The advantage to the straight uncuffed catheter is that it can be placed at the bedside and can be used soon after insertion. However, these catheters are more likely to become infected and/or develop leakage of fluids around the insertion site. For the patient who requires chronic dialysis, a catheter with two subcutaneous cuffs and the use of a downfacing exit site away from the diaper area and away from a gastrostomy tube are recommended (Auron et al.,

2007). As with all pediatric surgery procedures, the exact type of catheter and the timing and location of catheter insertion need to be tailored to the individual patient (Shahen et al., 2007). Repair of hernia (if present) should be performed at the time of catheter insertion.

Vascular access for HD requires a large (at least 7 French [F] but preferably an 8F) double lumen catheter that can be placed in the femoral or internal jugular vein. Double lumen catheters that are smaller than 7F are much more likely to develop problems during the dialysis procedure (Symons et al., 2007). Standard intravenous catheters are too flexible and too small to maintain patency with high blood flows. The use of 7F or 8F catheters is ideal; two 5F catheters in different sites can be lifesaving. If the need for dialysis is likely to last more than 1 week, a cuffed catheter is preferred to decrease the likelihood of infection. The length of the catheter should be chosen so that the tip of the catheter resides in the right atrium for internal jugular catheters and in the inferior vena cava for femoral catheters. Unless no other choices are available, the subclavian artery should not be used in infants who are likely to require long-term RRT because future forearm fistula of the ipsilateral arm can fail with “mild stenosis” of the subclavian vein.

Peritoneal Dialysis

Once PD access is placed and the decision to start dialysis has occurred, small volume continuous cycles (10 cc/kg) are performed. The dialysate solution is left dwelling in the peritoneal cavity, during which time solute and fluid removal takes place and is then drained. Continuous cycles are performed with each cycle lasting about an hour. The dextrose concentration in the fluid will determine the amount of net water loss (ultrafiltration). Complications associated with PD include peritonitis, leakage around catheter exit site, tunnel infection, catheter malfunction, and obstruction by omentum (Coulthard and Vernon, 1995). Leakage of fluid into other compartments (including the chest in patients without an intact diaphragm) can occur, and, if suspected, the fluid composition will reveal high glucose levels if a leak is indeed present. Absolute or relative contraindications to PD include NEC, abdominal wall defects, and the presence of an intra-abdominal foreign body, such as a ventriculoperitoneal shunt or diaphragmatic patch.

Hemodialysis

Once reliable access to the vascular space is achieved, the HD procedure can be performed. The two types of HD, intermittent HD and continuous RRT (CRRT), differ mainly by the duration of the procedure. Intermittent HD is significantly more efficient than CRRT. The blood flow and time on therapy are the limiting factors for solute clearance on HD. Even with the smallest dialyzers and neonatal tubing, most infants need blood priming of the extracorporeal circuit for the therapy. Skilled pediatric HD nurses are required at the bedside during the entire procedure, which typically lasts 3–4 hours. Achieving the adequate fluid removal necessary for the entire day can be difficult to achieve in the few hours on dialysis, especially in hemodynamically unstable infants. This technique usually requires systemic heparinization, with activated clotting time usually kept at 180 to 200 seconds, rendering the technique risky in preterm newborns and others at high risk for intracranial bleeding.

The main advantage to a continuous modality is that lower blood flow and fluid removal rates can be used to accomplish the desired ultrafiltration and clearance goals. Ronco et al. (1986) described

the use of CRRT in a critically ill newborn. CRRT requires a double lumen venous catheter whereby the CRRT pump pulls blood from one port of the catheter and returns the blood via the other side of the catheter. This is now a relatively common procedure in level IV NICUs.

Anticoagulation with CRRT is achieved with either systemic heparin or regional citrate anticoagulation. The advantage of regional citrate anticoagulation is that the patient is not systemically anticoagulated; however, this approach has the added risk of hypocalcemia caused from citrate excess (especially in those with impaired liver metabolism) and metabolic alkalosis (Tolwani and Wille, 2009). Because citrate is metabolized by the liver, caution must be exercised when dialyzing premature infants or newborns with multiorgan failure who may have impaired liver function.

Outcome data in neonates who require CRRT are scarce. Symons et al. (2003) reported a survival rate of 32/85 (37.6%) in neonates who received CRRT in five large children's hospitals in the United States. Between 2001 and 2007, the prospective pediatric CRRT group, a multicenter registry of 14 pediatric CRRT programs, reported outcomes for neonates in whom CRRT was initiated before 1 month of age (Symons et al., 2007). About 8% (35 neonates) in the registry were dialyzed in the first month of life. In this group, the median age was 8 days old; the median weight was 3.2 kg with the smallest infant weighing 1.3 kg. Of the 35 infants in the registry, 24 were dialyzed for either fluid overload, electrolyte imbalance, or both, and 11/35 were dialyzed for inborn errors of metabolism. Overall survival was 43%. Infants dialyzed for inborn errors had a better survival rate (73%) than the others (30%).

Several technical issues specific to infants arise when using CRRT for dialysis. The extracorporeal volume can incorporate greater than 50% of the infants' blood volume. For example, a 2.5-kg baby has a blood volume of 80 mL/kg (200 mL); the smallest circuit volume available on the most commonly used machine in the United States has an extracorporeal volume of around 100 mL, about 50% of infants' blood volume. Priming the blood circuit with blood will minimize the risks of hypotension during circuit initiation, but additional complications (acidosis, hypocalcemia, thrombocytopenia, and dilution of coagulation factors) make initiation of CRRT challenging. The risk for the bradykinin reaction that can occur at the initiation of CRRT with AN69 dialyzer (Baxter, Chicago, IL) membranes can be reduced using several techniques that minimize exposure of acidotic blood to the membrane (Brophy et al., 2001; Hackbarth et al., 2005).

Acute Kidney Injury as a Cause of Long-Term Chronic Kidney Disease

Total GFR is determined by the filtration rate of single nephrons and the number of nephrons present. When the number of nephrons is diminished, single nephron GFR increases as the kidney works to compensate for low nephron numbers. This compensatory hypertrophy causes glomeruli to function under increased intracapillary hydraulic pressure, which, over time, causes damage to capillary walls. This abnormal process leads to progressive glomerulosclerosis, proteinuria, hypertension, and CKD (Brenner et al., 1996). The hyperfiltration hypothesis has been applied and confirmed in autopsy data of hypertensive patients (Ohishi et al., 1995; Keller et al., 2003) and has been written about at length regarding infants with intrauterine growth restriction (Wadsworth et al., 1985; Barker and Osmond, 1988; Barker et al., 1989; Manalich et al., 2000;

White et al., 2009). A systematic review and metaanalysis in 2009 concluded that low birth weight babies (≤ 5.5 lbs) were 70% more likely to develop CKD later in life compared with individuals with normal birthweight (White et al., 2009).

Nephrogenesis continues through 34 weeks' gestation. Premature infants (even those born appropriate for GA) are therefore born with low nephron numbers compared with term infants. Using computer-assisted morphometry, Rodriguez et al. (2004) showed that premature infants who survived to at least 36 weeks' postconception had nephron numbers similar to premature infants with short survival, suggesting that the extrauterine environment does not support normal neoglomerulogenesis. In addition, preterm infants with AKI had fewer nephrons than similar infants without AKI.

Recent animal and epidemiology data suggest that AKI leads to CKD. As discussed in the section on the pathophysiology of ischemic AKI, tubular and vascular endothelial cellular damage occur with prolonged hypoperfusion. Animal models suggest that although tubular recovery occurs, damage to the vascular endothelial cells remains and can lead to interstitial fibrosis and progressive kidney dysfunction (Basile et al., 2001).

Studies of children with AKI show that over 50% have at least one sign of CKD 3–5 years after the inciting event. Large adult studies suggest that after AKI, rates of CKD (low GFR) are 5%–10%, with about 3%–5% developing ESRD.

The exact prevalence of CKD after neonatal AKI is unknown. Stapleton et al. (1987) reviewed the published single-center data and reported a 40%–88% prevalence of long-term CKD after oliguric renal failure. Since then, other retrospective small single-center studies describe similar tubular/glomerular dysfunction and hypertension in survivors of neonatal AKI (Chevalier et al., 1984; Polito et al., 1998; Abitbol et al., 2003). Outcome data on premature infants after AKI are scarce. Rodriguez et al. performed a cross-sectional study on premature infants during childhood born weighing less than 1000 grams and found that estimated GFR and tubular function were lower than in term-born children. Despite the limitations of these single-center studies, these data suggest that prematurity, intrauterine growth restriction, and AKI lead to a lower number of nephrons and/or endothelium dysfunction and an increased risk of long-term renal dysfunction. To further delineate the likelihood and extent that AKI causes CKD, and to provide guidelines for long-term follow-up, a prospective study is greatly needed. Future studies of interventions (such as ACE-Is) to decrease the rate of CKD progression in this growing population should be explored.

Renal Vascular Disease in the Newborn

Thromboembolic events in neonates usually result from an imbalance of the delicate homeostasis between bleeding and thrombosis. Some may be of genetic origin, some may relate to underlying stresses during pathologic processes, and some may relate to treatments for the pathologic processes.

Renal Arterial Thrombus

Incidence and Etiology

Renal artery thrombosis in the neonate is far less common than renal vein thrombosis. A major risk factor for renal arterial obstruction is umbilical artery catheterization. Other significant risk factors are shock, coagulopathy, and congestive heart failure. The reported incidence of umbilical artery-related thromboembolism reflects, in large part, the diagnostic test chosen. Doppler ultrasonography

estimates the incidence of umbilical artery-related thromboembolism from 14%–35%, whereas studies using angiography document incidences up to 64%. Autopsy studies have shown an incidence of umbilical artery-related thromboembolism between 9% and 28%, although major clinical symptoms of umbilical artery-related thromboembolism occur in 1%–3% of infants (Andrew et al., 2001). Trauma (endothelial injury) at the time of insertion of an umbilical artery catheter is postulated to be the cause of aortic thrombus formation, which then leads to thrombosis of one or both renal arteries.

High umbilical artery catheters, placed at the T6 to T10 vertebral level, have been associated with a decreased incidence of clinical vascular complications without a statistically significant increase in any adverse effects (Barrington, 2000b). The chances of umbilical artery catheter occlusion can be decreased by adding heparin to the infusing fluid at a concentration as low as 0.25 unit/mL (Barrington, 2000a).

Clinical Presentation

Clinical presentation varies with the extent and severity of thrombosis. Thrombosis of the abdominal aorta or renal arteries can manifest in any of the following ways: signs of congestive heart failure, hypertension, oliguria, renal failure, decreased femoral pulses with lower limb ischemia, or bowel ischemia/frank NEC secondary to superior or inferior mesenteric artery thrombosis. Symptoms of renal arterial thrombosis manifest within the first few postnatal days in a term neonate, compared with a median age of 8 days in a preterm neonate. The symptoms can be classified based on clinical severity; minor thrombosis with mildly decreased limb perfusion, hypertension, and hematuria; moderate thrombosis with decreased limb perfusion, hypertension, oliguria, and congestive heart failure; and major thrombosis with hypertension and multiorgan failure.

Laboratory findings associated with renal arterial thrombosis are thrombocytopenia, hypofibrinogenemia, elevated fibrin split products, variable prothrombin and thromboplastin times, conjugated hyperbilirubinemia, elevated blood urea nitrogen and creatinine, hyperreninemia, and hematuria.

Diagnosis

Doppler ultrasonography is used as the first line of imaging for diagnosing neonatal thrombosis although it usually fails to detect smaller intra-arterial thrombi and some larger asymptomatic venous thrombi (Roy et al., 2002). If ultrasonography is inconclusive, radionuclide imaging can be used. Angiography is the standard diagnostic modality and should be performed through the umbilical artery line if surgical intervention or fibrinolytic therapy is being considered.

Treatment

For asymptomatic or minimally symptomatic newborns, only supportive care is recommended, such as removal of the umbilical artery catheter and close ultrasonographic monitoring. Most of these thrombi resolve spontaneously. In newborns with mild signs of organ dysfunction and stable aortic and renal arterial thrombosis, management of hypertension, transient renal insufficiency, and mild congestive heart failure is recommended. Systemic heparin is given for anticoagulation. Close laboratory monitoring is done to avoid excessive heparinization, and clinical response is monitored by Doppler ultrasonography. The best method for monitoring heparinization remains controversial. (McDonald et al., 1981; Ignjatovic et al., 2006; Monagle et al., 2008; Newall et al., 2009).

Low molecular weight heparins (LMWHs) have some advantages over unfractionated heparin, thereby making them safe and efficacious alternatives to unfractionated heparin therapy. LMWHs have superior bioavailability, a longer half-life, and dose-independent clearance, which give a more predictable anticoagulant response. The incidences of heparin-induced thrombocytopenia and osteoporosis are rare with LMWHs; they can be used in neonates with poor venous access because they are administered subcutaneously. LMWHs also do not need frequent laboratory monitoring and dose adjustment (Albisetti and Andrew, 2002).

In case of potential life-threatening complications of aortic or renal thrombosis, fibrinolytic therapy (systemic or intrathrombotic) along with supportive care is indicated. There are limited data on efficacy, dose, and safety of fibrinolytic agents in infants (Manco-Johnson et al., 2002; Monagle et al., 2008). The intrathrombotic infusion of fibrinolytic agent reduces the cumulative dose and possible systemic adverse effects. Close monitoring by ultrasonography or angiography should be done to evaluate the response to this therapy. Fibrinolytic agents act by catalyzing the conversion of endogenous plasminogen to plasmin. The most commonly used agent is recombinant tissue plasminogen activator (tPA).

The major complication of tPA therapy is bleeding. Thrombocytopenia and vitamin K deficiency, if present, should be corrected before the start of treatment. Development of intraventricular hemorrhage or cerebral edema should be monitored closely. Mild bleeding secondary to fibrinolytic therapy can be stopped with local pressure. In the event of major bleeding, tPA should be stopped and intravenous fresh frozen plasma or cryoprecipitate should be given. The antifibrinolytic agent aminocaproic acid (Amicar) should be considered if the bleeding is life threatening.

Prognosis

The overall mortality rate with aortic and renal arterial thrombosis is between 9% and 20%, with mortality being higher with major aortic and renal arterial thrombosis (Nowak-Gottl et al., 1997). Renovascular hypertension is the most common long-term complication of renal arterial thrombosis. In most cases, these infants eventually are weaned from antihypertensive medications and remain normotensive. Another consequence of renal arterial thrombosis is chronic renal insufficiency caused by irreversible renal parenchymal damage; this is seen less frequently but always in cases with severe aortic and bilateral renal arterial thrombosis.

Renal Vein Thrombosis

Incidence and Etiology

Renal vein thrombosis (RVT) is the most common thrombosis in infancy and occurs primarily in the newborn period. It has an incidence of 2.2 cases per 100,000 live births (Bokenkamp et al., 2000). RVT has a male predominance of approximately 67%; it is unilateral in more than 70% of patients and more prevalent on the left side (approximately 63%). The thrombus also involved the inferior vena cava in approximately 43% of the cases, and it was associated with adrenal hemorrhage in approximately 15% (Dauger et al., 2009; Lau et al., 2007).

The cause of RVT is unknown, although a number of factors are associated with this disorder. Prothrombotic factors—including lupus anticoagulant, protein C, protein S, plasma antithrombin III activity, lipoprotein (a), factor V Leiden mutation, prothrombin gene mutation, and methylenetetrahydrofolate (*MTHFR*) thermolabile mutation—have a significant role in the pathogenesis of neonatal RVT (Kosch et al., 2004; Marks et al., 2005; Lau et al.,

2007). Other associated factors are maternal diabetes, traumatic delivery, prematurity, hyperviscosity, hypovolemia, hemoconcentration, sepsis, birth asphyxia, cyanotic congenital cardiac disease, congenital renal vein defects, and an indwelling umbilical venous catheter (Nowak-Gottl et al., 1997; Bokenkamp et al., 2000; Proesmans et al., 2005; Lau et al., 2007).

Clinical Presentation

There are three cardinal signs of RVT: macroscopic hematuria, palpable abdominal mass, and thrombocytopenia; these signs have been found in approximately 56%, 45%, and 47% of cases, respectively (Lau et al., 2007). Other signs and laboratory findings associated with RVT are oliguria or anuria, hemolytic anemia, metabolic acidosis, azotemia, and variable prothrombin and partial thromboplastin times.

Diagnosis

Renal ultrasonography is a useful and convenient way of diagnosing RVT. It shows unilaterally or bilaterally enlarged and echogenic kidneys with attenuation or loss of corticomedullary differentiation and little blood flow. In many cases, calcification and thrombus may be seen extending into the inferior vena cava (Proesmans et al., 2005). Doppler studies are useful for detecting resistance or absence of flow in renal venous branches and collateral vessels. Thrombosis in small intrarenal veins can cause increased resistance in renal arteries, even when blood flow in the main renal vein and its branches is normal (Lau et al., 2007). Length of the kidney has been reported to correlate negatively with renal outcomes (Winyard et al., 2006). Ultrasonography may also be used as a prognostic tool.

Although renal ultrasonography is the most commonly used imaging modality for diagnosing RVT, contrast angiography is considered the gold standard. Angiography, however, is invasive and requires exposure to ionizing radiation and can be performed only in a neonate in a stable condition. MRI has also been reported to give excellent diagnostic findings in RVT, although it should be reserved for those cases in which Doppler findings are inconclusive (Basterrechea Iriarte et al., 2008).

Treatment

Treatment of neonatal RVT remains controversial because there is not enough literature to compare supportive therapy with anticoagulation, fibrinolysis, or both. Supportive therapy should be provided to all affected infants in an attempt to correct any abnormalities in fluid, electrolyte, and acid–base balance. Hypertonic solutions, nephrotoxic medications, hyperosmotic radiographic contrast agents, and unnecessary use of diuretics should be avoided. Prophylactic heparin therapy has been recommended in a majority of cases to prevent thrombus extension by some authors (Dauger et al., 2009), whereas others report similar renal outcomes between supportive treatment and heparin therapies, including a similar proportion of atrophic kidneys secondary to RVT in neonates whether they were managed supportively or with heparin (Lau et al., 2007). LMWH is being used more frequently than unfractionated heparin for anticoagulation. Fibrinolysis is usually reserved for more severe cases, such as bilateral thrombosis and systemic effects (Dauger et al., 2009). Whichever the treatment approach, affected neonates must be followed closely for renal complications such as hypertension, chronic renal insufficiency, and renal atrophy.

Surgical interventions such as thrombectomy or nephrectomy have not shown any benefit. Thrombectomy prevents the main

thrombus from extending into the inferior vena cava or contralateral kidney, but it does not prevent renal infarction because smaller intrarenal veins are almost always involved.

Prognosis

Renal scarring and atrophy are well-recognized complications of RVT in the affected kidney, which can be assessed with a radio-nuclide scan. Approximately 19% of patients have persistent elevation of blood pressure, which has been shown to be slightly higher—at 21% for those with bilateral RVT. The mortality rate for neonates with RVT is approximately 3% (Lau et al., 2007). Most of the deaths are due to underlying disease and not RVT or secondary renal dysfunction. Because more than 80% of neonates with RVT have shown persistent abnormalities on renal imaging and there are not enough data on long-term outcome of such neonates, continued follow-up is strongly recommended.

Renal Cortical and Medullary Necrosis

Incidence and Etiology

Renal cortical and medullary necrosis is uncommon in newborns and usually encountered in critically ill newborns as a manifestation of perinatal and postnatal stress leading to end-organ injury. It is usually diagnosed on autopsy or manifested as elevated and persistent kidney dysfunction. The incidence is 5% in infants who die at less than 3 months of age (Lerner et al., 1992). Risk factors associated with renal cortical and medullary necrosis are congenital heart disease, perinatal anoxia, placenta abruption, twin–twin or twin–maternal transfusions, sepsis, infectious myocarditis, vascular malformations, dehydration, prematurity, respiratory distress syndrome, bleeding diathesis, cardiac catheterization, and intravenous contrast agents (Nygren et al., 1988; Lerner et al., 1992).

Pathophysiology

Medication administration, blood loss, and ischemia can interfere with compensatory mechanisms to maintain renal perfusion and can lead to acute tubular necrosis that, depending on the severity of the insult, then may lead to vasculature injury and microthrombi formation with subsequent renal cortical and medullary necrosis. Administration of ACE-Is in the context of hypoperfusion can decrease the perfusion pressure in the glomerulus and can precipitate acute renal failure and, eventually, renal cortical necrosis.

Clinical Presentation

The clinical manifestations include hematuria, oliguria, rising SCr, and renal enlargement, which are nondiagnostic and associated with many other common neonatal renal abnormalities. Because renal cortical and medullary necrosis usually develops in critically ill newborns in the setting of shock, this needs to be explored in all critically ill neonates with abnormal renal function.

Diagnosis

In renal cortical and medullary necrosis, laboratory features may be present, such as hematuria, elevated blood urea nitrogen and creatinine, and thrombocytopenia. Renal ultrasound examination results are normal initially but may show small kidneys that are hyperechoic for age, loss of corticomedullary differentiation, and progressive decreased kidney size. A radionuclide renal scan shows decreased to no perfusion with delayed or no function (Andreoli., 2004).

Management and Prognosis

Infants with cortical necrosis may have partial recovery or no recovery at all. Typically they need RRT, short-term or long-term, but those who recover enough renal function to be managed without dialysis are at risk for late development of chronic renal failure.

Chronic Kidney Disease

Neonatal CKD is diagnosed when sustained derangements of glomerular filtration or tubular function occur with minimal to no resolution over time. In many cases, CKD follows AKI, and in others the acute phase of the renal compromise has not been detected or has occurred in utero, often as a result of anatomic abnormalities (e.g., hypoplasia, dysplasia, malformations). In that setting, the diagnosis of CKD is established without documented evidence of preexisting AKI. According to guidelines published by the Kidney Disease Outcomes Quality Initiative (KDOQI), CKD is present if there is evidence of kidney damage for more than 3 months, as defined by structural or functional abnormalities, with or without decreased GFR, or a GFR less than 60 mL/min per 1.73 m² for more than 3 months in children older than 2 years with or without kidney damage. These guidelines do not apply to infants less than 2 years of age, as a result of ongoing maturation of the kidney and improvement in GFR over the first 2 years of life. In turn, the KDIGO guidelines from 2012 recommend that for the classification of CKD in neonates and infants, available normative values and conventionally accepted equations should be used to classify neonatal CKD into one of three categories: normal (GFR <1 standard deviation [SD] below the mean); moderately reduced (GFR >1 SD to ≤2 SD below the mean); or severely reduced (GFR >2 SD below the mean) (Zaritsky and Warady, 2014).

Currently, the updated Schwartz formula derived using iohexol clearance and enzymatically measured creatinine is the most commonly used equation to estimate GFR using SCr; however, that equation is based on data derived from children greater than 1 year of age (Schwartz et al., 2009). Recent studies suggest that equations incorporating the use of cystatin C, renal mass, and body surface area may provide a more accurate assessment of GFR, at least for neonates (Treiber et al., 2015). ESRD, the point at which dialysis or kidney transplantation is necessary to ameliorate the physiologic complications of uremia owing to kidney failure, represents the most severe stage of CKD. The pathophysiologic mechanisms leading to the progression of AKI to CKD and ESRD are discussed earlier in this chapter.

Epidemiology

There is little information on the incidence and prevalence of CKD in neonates and infants, due to the lack of a uniform definition. In one small study, the estimated incidence of CKD was 1:10,000 live births with a male to female ratio of 2.8:1. The most common causes of CKD in neonates are renal dysplasia and obstructive uropathy (Wedekin et al., 2008; Mekahli et al., 2010; Harambat et al., 2012; Carey et al., 2015). The male predominance results from the finding that posterior urethral valves are the most frequent congenital obstructive disorder. In a small German study, 53% of children with CKD were premature, a figure significantly higher than the rate experienced by the total infant population of Germany (Wedekin et al., 2008). A publication from the Chronic

Kidney Disease in Children (CKiD) cohort also revealed a high prevalence of children with CKD who had an abnormal birth history as defined by low birth weight (17%), small for GA (14%), or prematurity defined as GA less than 36 weeks (12%) (Greenbaum et al., 2011). In a study of more severe CKD, 35% of affected patients were born prematurely, and approximately 50% had a comorbidity, such as cardiopulmonary and/or neurologic involvement (Mekahli et al., 2010).

Most epidemiologic reports focus on the development of ESRD in this age group. These studies demonstrate a varying regional incidence of ESRD, and the worldwide incidence is unknown. In one study, the estimated incidence of neonatal ESRD in the United States and Canada was 0.32 in 100,000 live births (Carey et al., 2007). The European Registry for Children on Renal Replacement Therapy collects data from many countries across Europe and recently reported the incidence of ESRD in children aged 0–4 years to be around 5.2 per million children (Chesnaye et al., 2015). The incidence in the 0–4 years age group as reported by the United States Renal Data System was 10.3 per million US population in this age group. This age group makes up between 10%–20% of all children who receive RRT (dialysis and transplantation) (Assadi, 2013; Borzych-Duzalka et al., 2013). Studies show that wealthier countries, those that spend more on health care, and countries where patients pay less out of pocket expenses have higher rates of RRT initiation. Thus much of the variability is likely explained by socioeconomic factors and less by genetic susceptibility to renal disease (Chesnaye et al., 2015).

Clinical Sequelae

Pathophysiology of Anemia

Anemia is a frequent complication of CKD in infants and children, and the prevalence of anemia increases with worsening stages of CKD. Recently, a study by Atkinson et al. (2010) revealed that 73% of pediatric patients with CKD stage 3 (GFR 30–59 mL/min per 1.73 m²) were anemic. This percentage increased to 93% of those with CKD stage 5 (GFR <15 mL/min per 1.73 m² or dialysis). The anemia of CKD is an important predictor of patient morbidity and mortality. It is associated with a number of physiologic abnormalities, including decreased tissue oxygen delivery, increased cardiac output, cardiac enlargement, ventricular hypertrophy, congestive heart failure, and impaired immune responsiveness (Gafer et al., 1994; Mitsnefes et al., 2000; Borzych-Duzalka et al., 2013). There is also evidence to suggest that the presence of anemia is associated with an increased risk of hospitalization in children with CKD (Staples et al., 2009).

The pathophysiology of anemia in infants and young children with CKD is primarily the result of a decrease in the renal production of erythropoietin, iron deficiency, or both (Koshy and Geary, 2008). Other potential contributing factors include a shortened red blood cell life span, secondary hyperparathyroidism, hypothyroidism, folate and vitamin B₁₂ deficiency, chronic inflammation, and hemoglobinopathies. In the early stages of CKD, iron deficiency tends to be common, and in one study of pediatric CKD patients, Baracco et al. (2011) found that 25% of patients with CKD stage 2 and 55% of patients with stage 3 CKD had iron deficiency. The cause of absolute iron deficiency is multifactorial and can be related to poor intake, gastrointestinal blood loss, and repeated phlebotomies for laboratory tests.

Erythropoietin deficiency becomes more prevalent in the later stages of CKD. Children may also be particularly prone to factors that contribute to relative erythropoietin resistance including

hyperparathyroidism, aluminum toxicity, and hemolysis (Bamgbola 2011). The decreased erythropoietin production from the kidney ultimately leads to anemia through increased apoptosis of red blood cell precursors in the bone marrow, often accompanied by iron deficiency related to the factors listed above, as well as an increased production and decreased excretion of hepcidin (Atkinson and Furth, 2011; Ganz and Nemeth, 2016).

Management of Anemia

According to the KDOQI *Clinical Practice Guidelines and Clinical Practice Recommendations for Anemia in Chronic Kidney Disease* produced by the National Kidney Foundation, anemia is defined as an Hgb concentration less than the fifth percentile of normal for age and sex (Table 90.8) (KDOQI, 2007). The normative values used to define anemia in children older than 1 year are taken from the third National Health and Nutrition Examination Survey (Astor et al., 2002) database, whereas the norms for infants younger than 1 year are derived from other reference sources (Nathan, Orkin, 2003). Recently, KDIGO released recommendations for the diagnosis of anemia in CKD that defined anemia as Hgb less than 11.0 g/dL in children 0.5–5 years (KDIGO Group, 2012).

The KDOQI guidelines recommend checking Hgb in all patients with CKD at least annually. In those children found to be anemic, the initial work-up should include red blood cell indices, reticulocyte count, white blood cell count with differential and platelet count, and iron parameters (serum iron, total iron binding capacity, and serum ferritin). These guidelines also recommend targeting an Hgb level between 11.0 and 13.0 g/dL as part of anemia management in pediatric patients with CKD (KDOQI and National Kidney Foundation, 2006; KDOQI, 2007). Erythropoiesis-stimulating agents (ESAs) such as recombinant erythropoietin- α (EPO) and darbepoetin, an analogue of erythropoietin with a longer half-life, along with iron supplements, are the key elements of anemia management in CKD. Both ESAs appear to have equal efficacy and similar safety profile (Hattori et al., 2014; Schaefer et al., 2016) and have been studied in premature infants (Ohls et al., 2013). When treated with an ESA, infants and young children

generally require larger doses than older children and adults, despite having a higher capacity for hematopoiesis. Whereas the average dose of EPO for children with CKD is 200–250 units/kg per week given by the subcutaneous route, younger children (<1 year) often require doses as high as 400 units/kg three times per week. This dose discrepancy holds true for patients receiving dialysis as well. Infants on dialysis have required doses averaging from 300–350 units/kg per week compared with those patients greater than 12 years whose dose averages around 200 units/kg per week. Children receiving HD typically require more EPO than patients receiving PD, as a result of the blood loss that routinely occurs with HD.

Iron therapy typically consists of the provision of oral elemental iron in doses ranging from 2 to 3 mg/kg per day up to 6 mg/kg per day in two to three divided doses (KDOQI and National Kidney Foundation, 2006). Iron should be taken 2 hours before or 1 hour after all calcium-containing phosphate binders in patients with CKD and a history of hyperphosphatemia to maximize gastrointestinal absorption. In HD patients, intravenous iron administration is often recommended because of inadequate iron absorption after oral administration coupled with increased losses of blood and iron during the HD treatments. Levels of serum ferritin greater than 100 ng/mL and transferrin saturation values greater than 20% are believed to reflect adequate iron stores in patients with CKD (KDOQI and National Kidney Foundation, 2006).

Growth and Development

Children with CKD often experience some degree of growth failure, which may start as early as CKD stage 3 (Hamasaki et al., 2015). The cause of the disordered growth in patients with CKD is a multifactorial process. Protein-calorie malnutrition, metabolic acidosis, electrolyte disarray, renal osteodystrophy, changes in the gonadotropic hormone axis in the face of uremia, and corticosteroid treatment are all factors that contribute to this challenging problem (Haffner, 2008).

The growth failure that exists is especially concerning when CKD occurs in infancy, a time that is normally characterized by rapid growth. Many studies have demonstrated already delayed growth at the time of dialysis initiation that has persisted through at least the first year following dialysis initiation (van Stralen, 2011; Borzych-Duzalka et al., 2014). Young children on dialysis have historically often failed to grow normally, despite meeting 100% of the recommended daily allowance of caloric and protein intake (Shroff et al., 2003; Stańczuk et al., 2016). Thankfully, growth outcomes of infants with ESRD have improved over time, possibly because of advances in medical, nutritional, and surgical therapies (Ledermann et al., 1999; Hijazi et al., 2009). Recent reports have also described improved longitudinal growth and sustained catch-up growth in infants with CKD in whom recombinant growth hormone treatment was initiated in the first year of life. Similar results have also been obtained with intensive nutritional regimens (Fine et al., 1995; Maxwell, 1996; Mencarelli et al., 2009; Santos et al., 2010; Rees, 2015). Finally, growth outcomes regularly improve after transplantation in young patients in whom accelerated growth may occur (Fine et al., 2010; NAPRTCS, 2014).

Renal impairment in infancy, a crucial time of neural development, raises concerns regarding the neurodevelopmental outcomes in children with ESRD. Advanced CKD has been linked to poor neurocognitive function in the areas of attention, memory, and inhibitory control (Hooper et al., 2011; Ruebner et al., 2015). Recently, small studies examining the effect of ESRD during infancy on neurocognitive development have suggested that there may be minor delays in intellectual and metacognitive function but that

most children without other comorbidities do not experience significant developmental delay (Johnson and Warady, 2013). Other comorbidities of CKD (e.g., anemia, iron deficiency, hypertension, cerebral vascular accidents, adverse effects of therapy) have been implicated in the neurodevelopmental impairments in many patients, and these comorbidities may explain the association between duration of CKD and impaired executive function (Geary, 1998; Lande et al., 2011; Johnson and Warady, 2013; Mendley et al., 2015). Genetic syndromes involving the central nervous system may also influence neurocognitive outcomes for these patients (Verbitsky et al., 2015). While larger studies are needed to provide additional data, it is clear that neurocognitive outcomes have improved for infants with ESRD over the past two decades, likely related to improved dialysis techniques, better nutrition, and avoidance of exposure to aluminum (Andreoli et al., 1984; Freundlich et al., 1985).

Nutrition

Nutritional Assessment

The origin of malnutrition in children with CKD is multifactorial; however, an inadequate voluntary intake is considered a major contributing factor, especially in infants. Nausea and vomiting are common in infants and children with CKD, with delayed gastric emptying and gastroesophageal reflux detected in as many as 75% of patients with these problems (Ruley et al., 1989). Protein energy wasting (PEW) is a common problem in patients with CKD and may be another major contributor to poor growth in the first few years of life. The International Society of Renal Nutrition and Management has identified specific biochemical evidence (i.e., low albumin, cholesterol, or transthyretin), reduced body mass index, and reduced muscle mass as the primary characteristics of PEW in adults (Fouque et al., 2008; Ingulli and Mak, 2014). Additional studies specific to the pediatric CKD and dialysis population have confirmed the importance of these factors, along with short stature as features characterizing PEW. Whereas few body composition studies of very young CKD patients have been performed, weight-for-length is often below average for infants with CKD who have not received calorie supplements, and small studies suggest that infants with CKD may have lean muscle mass deficits (Foster et al., 2012). However, the most prominent feature of inadequate nutrition in this population is linear growth restriction (KDIGO, 2009). Modified PEW scores as a reflection of poor nutrition in pediatric patients have also been associated with an increased risk for hospitalization, disease progression, and neurocognitive complications (Abraham et al., 2014).

In view of the importance of nutritional status to the outcome of the infant and young child with CKD, frequent monitoring of the patient is mandatory. Collaboration with a pediatric renal dietician is beneficial to assist in the nutritional evaluation and treatment strategy. An age-related schema for parameters and frequency of nutritional assessment for patients with CKD has recently been published (Table 90.9) (KDIGO, 2009). The World Health Organization Growth Standards of length-for-age, weight-for-age, weight-for-length, body mass index-for-age, and head circumference-for-age should be used as the reference for children from birth to 2 years (WHO, 2006). Nutritional intervention is indicated in children with CKD when there are findings that include an impaired ability to ingest or tolerate oral feedings, a body mass index value less than the fifth percentile of height-for-age, an acute weight loss of 10% or more, or a length/height ratio more than two SDs less than the mean. However, neonates with

TABLE 90.10 Equations to Estimate Energy Requirements for Children at Healthy Weights

| Age (months) | EER (kcal/d) = Total Energy Expenditure + Energy Deposition |
|--------------|---|
| 0–3 | EER = $[89 \times \text{weight (kg)} - 100] + 175$ |
| 4–6 | EER = $[89 \times \text{weight (kg)} - 100] + 56$ |
| 7–12 | EER = $[89 \times \text{weight (kg)} - 100] + 22$ |
| 13–35 | EER = $[89 \times \text{weight (kg)} - 100] + 20$ |

EER, Estimated energy requirement.
Modified from National Kidney Foundation. KDOQI Clinical Practice Guideline for Nutrition in Children with CKD: 2008 Update. *Am J Kidney Dis.* 2009;53:S36.

CKD should be considered to be at nutritional risk if they are preterm or are characterized by any of the following:

- Low birth weight (<2500 g)
- A birthweight *z* score less than –2 SD for GA
- Polyuria and associated renal salt wasting

Nutritional Management

In children with CKD, the spontaneous energy intake decreases with deteriorating kidney function. Energy intake is the principal determinate of growth during infancy. Energy requirements should, in turn, be considered to be 100% of the estimated energy requirement for chronologic age (Table 90.10) (Ruley et al., 1989; National Academies Press, 2002; KDOQI, 2009; Foster et al., 2012). Malnutrition has the most marked negative effect on the growth of children with congenital disorders leading to CKD. Supplemental nutritional support is indicated when the voluntary intake by the child fails to meet energy requirements and the child is not achieving expected rates of weight gain or growth for age. In infants requiring fluid restriction because of their impaired kidney function, oral intake of an energy-dense diet with a milk formula that has a caloric density greater than 20 kcal/oz and the appropriate phosphorus content for CKD stage is preferred. If poor appetite or vomiting preclude an adequate oral intake, tube feedings (e.g., nasogastric, gastrostomy, gastrojejunostomy) should be considered

and provided by either bolus or continuous infusion. The development of repeated emesis in children fed per nasogastric tube has prompted the use of gastrostomy as the preferred route of therapy (Warady et al., 1996). In infants younger than 1 year, an initial infusion rate of 10 to 20 mL/hour or 1 to 2 mL/kg per hour is generally well tolerated, to be followed by a daily increase of 5 to 10 mL per 8 hours or 1 mL/kg per hour toward achieving the treatment goal. It is imperative that tube-fed infants be encouraged to continue some oral intake or have oral stimulation (e.g., pacifier) if persistent feeding dysfunction is to be prevented.

Whereas the spontaneous dietary protein intake (DPI) is reduced in progressive CKD in a manner similar to that of energy intake, the DPI of the patient with CKD is typically far in excess of the average requirements. At the same time, there is no evidence that strict dietary protein restriction has any nephroprotective effect (Chaturvedi and Jones, 2007), whereas aggressive restriction has been noted to compromise the growth of infants with CKD (Uauy et al., 1994). Because moderate dietary protein restriction reduces the accumulation of nitrogenous waste products, decreases acid load, and helps to lower dietary phosphorus intake (which helps preclude bone-mineral and cardiovascular complications), it is appropriate to gradually lower the DPI toward 100% of the dietary reference intake (DRI) as CKD progresses toward the need for dialysis (Ruley et al., 1989). More specifically, a DPI of 100%–140% DRI for CKD stage 3, 100%–120% DRI for CKD stage 4 to 5, and 100% DRI for CKD stage 5D (dialysis) have been proposed (Table 90.11) (KDOQI, 2009). In patients receiving dialysis, the dietary protein requirements are increased to account for dialysis-related protein losses.

Acid–Base and Electrolytes

Fluid and electrolyte requirements of children with CKD vary according to their primary kidney disorder and the degree of residual kidney function. Infants and children normally have a relatively larger endogenous hydrogen ion load (2–3 mEq/kg) than adults, resulting in metabolic acidosis as a common manifestation of CKD in children and an important negative influence on growth. Metabolic acidosis leads to changes in bone composition and decreases in 1,25-(OH)₂D synthesis, in addition to endogenous growth hormone and recombinant growth hormone resistance (de-Brito Ashurst et al., 2015). Based on the experience of successfully

TABLE 90.11**Recommended Dietary Protein Intake for Children with Chronic Kidney Disease Stages 3 to 5 and 5d**

| Age | DRI (g/kg per day) | DRI | | | |
|-------------|--------------------|--|---|--|--|
| | | Recommended for CKD Stage 3 (g/kg per day) (100%–140% DRI) | Recommended for CKD Stages 4–5 (g/kg per day) (100%–120% DRI) | Recommended for HD (g/kg per day) ^a | Recommended for PD (g/kg per day) ^b |
| 0–6 months | 1.5 | 1.5–2.1 | 1.5–1.8 | 1.6 | 1.8 |
| 7–12 months | 1.2 | 1.2–1.7 | 1.2–1.5 | 1.3 | 1.5 |
| 1–3 years | 1.05 | 1.05–1.5 | 1.05–1.25 | 1.15 | 1.3 |

^aDRI + 0.1 g/kg per day to compensate for dialytic losses.
^bDRI + 0.15–0.3 g/kg per day depending on patient age, to compensate for peritoneal losses.
 CKD, Chronic kidney disease; DRI, dietary reference intake; HD, hemodialysis; PD, peritoneal dialysis.

enhancing the growth of infants and children with isolated renal tubular acidosis with alkali therapy (McSherry and Morris, 1978), it is recommended that children with CKD be treated to achieve a serum bicarbonate level of at least 22 mmol/L (KDOQI, 2009). A recent publication from the CKiD study revealed that a serum bicarbonate less than 18 mmol/L was a risk factor for poor growth. The fact that a minority of the children with a low bicarbonate level were receiving supplemental bicarbonate therapy emphasizes the importance of being vigilant with respect to evaluation and treatment (Rodig et al., 2014). In recent studies in adults with CKD, correction of metabolic acidosis led to a decreased rate of CKD progression (de Brito-Ashurst et al., 2009; Mahajan et al., 2010; Phisitkul et al., 2010). This finding may translate to the pediatric population as well, but further studies are required.

Whereas restriction of sodium and water is often indicated in children with CKD complicated by sodium and fluid retention and systemic hypertension, infants and children with CKD secondary to obstructive uropathy or renal dysplasia are often polyuric and may experience substantial urinary sodium and water losses despite experiencing advanced stages of CKD. Infants and children with salt-wasting forms of CKD who do not receive salt supplementation may in turn experience extracellular volume contraction, vomiting, constipation, and significant growth retardation (Parekh et al., 2001). The same holds true for infants receiving PD, with or without polyuria, as most patients lose significant quantities of sodium in the dialysate. Sodium depletion in the infant PD population has resulted in hypotension, cerebral edema, and blindness (Lapeyraque et al., 2003). Individualized therapy can, in turn, be achieved by first prescribing at least the age-related DRI of sodium and chloride (Table 90.12), with subsequent modification of therapy based on regular assessment of clinical and laboratory data. In PD patients, a dialysis sodium balance study may be performed to formally assess sodium losses through dialysis to help guide sodium supplementation (Foster et al., 2012). Close monitoring of blood pressure is imperative because, as noted previously, episodes of severe hypotension in young infants on PD have been associated with tragic neurologic complications.

Potassium homeostasis in children with CKD is usually unaffected until the GFR falls to less than 10% of normal. However, infants and children with disorders such as renal dysplasia and reflux nephropathy often demonstrate renal tubular resistance to aldosterone and may experience hyperkalemia, even when the GFR

is preserved. The hyperkalemia can be exacerbated by volume contraction, as can be seen in patients with salt-wasting forms of CKD. In patients who remain hyperkalemic despite repletion of salt and water, restriction of dietary potassium intake is critical. For infants and young children, the provision of 40 to 120 mg (1–3 mmol/kg per day) of potassium may be a reasonable place to start. Breast milk has a lower potassium content (546 mg/L; 14 mmol/L) than commercial milk-based infant formula (700–740 mg/L; 18–19 mmol/L) and may be preferred (KPOQI, 2009). Pretreatment of infant formula with a potassium binder such as sodium polystyrene sulfonate may also help address hyperkalemia in infants. Typically, 0.5 to 1.5 g of sodium polystyrene sulfonate is added to every 100 mL of formula or expressed breast milk. Recent studies suggest that this therapy significantly alters the composition of other electrolytes in a formula-dependent manner and mandates close monitoring. Calcium supplementation and sodium restriction may be required (Thompson et al., 2013). The powdered form of sodium polystyrene sulfonate is also recommended due to the presence of a high aluminum concentration in liquid preparations (Taylor et al., 2015). Constipation and certain medications (e.g., potassium-sparing diuretics, ACE-Is, angiotensin-receptor blockers) may exacerbate hyperkalemia in infants with CKD and should be addressed. Finally, the use of potassium-wasting diuretics

(e.g., furosemide) may also be utilized for the treatment of hyperkalemia in those patients who have urine output (Bunchman et al., 1991; Fassinger et al., 1998).

Renal Osteodystrophy

Infants with CKD and secondary hyperparathyroidism may experience improvement subsequent to the initiation of RRT. One study followed 17 patients initiating HD between birth and 2 years of age and found that the percentage of patients with intact parathyroid hormone (iPTH) concentrations less than twice the upper limit of normal increased after 3 months of HD (41% at initiation vs 69% after 3 months) (Shroff et al., 2003). Another study of 20 infants on long-term PD revealed similar results (58% after 6 months of PD vs. 100% after 1 year of PD) (Ledermann, 2000). Further study regarding the prevalence of renal osteodystrophy in this population is needed.

Renal Replacement Therapy

ESRD is an uncommon disorder in children less than 4 years of age, with an incidence of 5.2–10.3 per million age-related population (Chesnaye et al., 2015). Neonatal ESRD is even less common with an incidence of approximately 0.32 per 100,000 live births (Carey et al., 2007). A large international registry study of neonates on RRT showed that they made up between 6.8% and 18.3% of all infants less than 2 years of age on dialysis. Major causes of ESRD in the 0 to 2-year age group include congenital anomalies of the kidney and urinary tract and cystic kidney disease (van Stralen et al., 2014). Although kidney transplantation is the nearly universal goal for children who develop ESRD, data from the most recent North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) annual report revealed that 80% of children under 2 years old who received a renal transplant also received chronic dialysis before transplantation (NAPRTCS, 2014).

Peritoneal Dialysis

PD is the preferred chronic dialysis modality for infants with ESRD. A recent publication from NAPRTCS has shown that greater than 90% of patients 0 to 1-year-old receiving dialysis were receiving PD at dialysis initiation (NAPRTCS 2011; Carey et al., 2015). The mechanics of chronic PD (CPD) are similar to those discussed above for acute PD. While the CPD prescription initially mirrors that of acute PD, the fill volume is subsequently titrated upwards during CPD to a goal of 600 to 800 mL/m² body surface area in infants during each exchange; the duration of the dwell is adjusted to reach predefined adequacy metrics in terms of solute and fluid removal (National Kidney Foundation, 2006).

The complications of PD are similar for acute and chronic PD. The single most serious complication is peritonitis, which occurs more frequently in infants than older children (NAPRTCS, 2011; Sethna et al., 2016). Some data suggest that peritonitis is increased in infants with oligoanuria (Vidal et al., 2012). Whereas gram-positive organisms account for the majority of infections, gram-negative episodes of peritonitis are common in infants and young children (Zurowska et al., 2008), and the percentage of gram-negative and polymicrobial peritonitis episodes may be on the rise (Hijazi et al., 2009). Empiric therapy for peritonitis should, in turn, always provide coverage for gram-positive and gram-negative organisms (Warady et al., 2012). Other CPD-related complications that occur most frequently during infancy include anterior ischemic

optic neuropathy and sudden blindness secondary to hypovolemia, excessive loss of protein across the peritoneal membrane, and hernia formation (Quan and Baum, 1996; Lapeyraque et al., 2003; Hijazi et al., 2009).

Hemodialysis

The use of HD during infancy is most often dictated by the presence of a medical condition (e.g., omphalocele, gastroschisis, diaphragmatic hernia, bladder exstrophy) that compromises the ability to use the peritoneal membrane as a dialyzing membrane. The HD procedure during infancy is complicated, and limited clinical experience has revealed a high incidence of patient morbidity (Al-Hermi et al., 1999; Shroff et al., 2003; Kovalski et al., 2007). As noted above, the complicated nature of the HD procedure mandates that it is performed only in highly qualified centers with access to pediatric dialysis expertise. Recent studies of complications for infants on chronic HD reveal improvement in central venous catheter life in recent years but continued high rates of hypertension, psychomotor retardation, and hospitalization (Feinstein et al., 2008; Quinlan et al., 2013; Pollack et al., 2016).

Transplantation

The topic of kidney transplantation in patients who develop ESRD as neonates or young infants is complicated, and a lengthy discussion is beyond the scope of this chapter. In short, however, transplantation is a viable alternative for these young patients and is their best hope for long-term survival. In a review of NAPRTCS data, 20% of 0 to 1-year-olds and 24% of 2 to 5-year-olds with ESRD received a preemptive (e.g., no prior dialysis) transplant. Only eight infant transplants (<1 year of age) have been performed and entered into the NAPRTCS registry since 2008 (NAPRTCS, 2014). The overall transplant rates and graft survival rates for some of the largest and most recent studies of outcomes in neonates or young children with ESRD are listed in Table 90.13. Graft survival in patients who developed ESRD as neonates or infants has improved (Carey et al., 2015), and the rates of graft survival for the two groups are similar. These improvements in transplant rates and graft survival likely contribute to the improved overall survival of these patients and likely will improve further as outcomes in regards to other comorbidities, such as cardiovascular disease and growth, also improve.

What is often most important for the neonatologist is recognition of the need to develop a collaborative strategy with members of the pediatric nephrology, surgery, and urology teams for management of congenital structural abnormalities of the urinary tract that are present in the patient with severe CKD/ESRD, the majority of whom will ultimately require dialysis and transplantation (Sarwal, Salvatierra, 2004).

Outcomes

Hospitalization

There is emerging evidence to support the clinical expectation that a majority of neonates and infants with CKD or ESRD require frequent hospitalization throughout childhood. In one study of 18 children requiring chronic HD by 2 years of age, the median number of hospital admissions while receiving dialysis was 6 (range 3 to 16). Of those hospitalized, the median hospitalization rate per patient was 8.2 admissions per year with the duration of hospitalization ranging from 63 to 399 days (Shroff et al., 2003).

Another study divided 698 children requiring chronic dialysis within the first 2 years of life into those initiating dialysis by 1 month of age and those initiating dialysis between 1 month and 24 months of age. Approximately 80% of children in both groups required hospitalization at some point in the 13-year follow-up period. Among children ever hospitalized, those initiating dialysis as neonates were hospitalized more frequently than were children starting dialysis later (mean number of hospitalizations 54 vs 39; *P* < .001) and experienced longer hospital stays (Carey et al., 2007).

Survival

Long-term survival of neonates with ESRD appears to be approaching that of older infants and young children. In several recent studies examining medium-term survival of neonates, infants, or

young children who started dialysis, the overall survival rates ranged from 70%–87% (Table 90.13) (Carey et al., 2007; Hijazi et al., 2009; Mekahli et al., 2010; van Stralen et al., 2014; Carey et al., 2015). Neonates on dialysis had only slightly lower survival rates compared with older infants and children (Carey et al., 2007; Carey et al., 2015). The main reasons for death included infection and cardiovascular disease. Concomitant neurologic disease and other comorbidities were associated with increased mortality (Mekahli et al., 2010; van Stralen et al., 2014). Studies that examined multiple time periods showed improved survival for neonates and infants in more recent years (Carey et al., 2007; Carey et al., 2015). Although the recent large studies suggest a good medium-term survival and support the recommendation for RRT in these complex patients, more long-term data are clearly needed.

Ethics of Initiating or Withdrawing Renal Replacement Therapy

Decisions to withdraw or withhold treatment have to be made for many patients in neonatology units and for as many as 30%–58% of patients in pediatric intensive care units. The conceptual framework for medical decision making in seriously ill newborns attempts first to classify the anticipated therapy and outcomes as clearly beneficial, clearly futile, or of uncertain benefit. While families should be active participants in medical decision making, physicians may override a family's wishes in situations deemed clearly beneficial or clearly futile.

RRT for neonates and very young infants has long been considered of uncertain benefit due to unclear long-term outcomes. In turn, medical providers have often deferred to family members with regards to decisions about dialysis initiation and withdrawal in young patients. However, as dialysis has become more routinely offered to neonates and infants with ESRD and more published data on improved medium-term and long-term outcomes have become available, consideration has been given to classifying this therapy as clearly beneficial (Lantos and Warady, 2013). Nevertheless, few studies have directly examined the changing attitudes of medical providers on this issue. Geary and colleagues initially conducted an international survey on the attitudes of pediatric nephrologists regarding the management of ESRD during infancy nearly two decades ago (Geary, 1998). More than 200 physicians from eight countries replied to a series of questions pertaining to the provision of RRT to neonates younger than 1 month of age versus those 1 to 12 months old. At that time, 93% of respondents stated that they would offer dialysis to some patients less than 1 month of age, 41% would offer it to all patients less than one month of age, and 50% believed it was usually ethical for families to withhold RRT. In a follow-up study conducted by the same group using an almost identical survey 10 years later, 98% of pediatric nephrologists responded that they would offer dialysis to some patients less than 1 month of age, although only 30% of pediatric nephrologists would offer it to all patients less than one month of age. Additionally, there was a 25% increase compared with the earlier survey in those who thought it was the parents right to “usually” refuse RRT in neonates (Teh et al., 2011). In both studies, physicians responded that they more routinely provided dialysis to the older than 1-month to 12-month age group and thought it was less acceptable for families to refuse dialysis initiation for children of this age (Geary, 1998; Teh et al., 2011). The factors that most often influenced the decision to initiate or withhold RRT were the presence of coexistent serious medical disorders and the anticipation of significant morbidity for the child (Geary, 1998; Teh et al., 2011). Evidence for this age-related variation in

philosophy and practice has been seen in other surveys as well (Fauriel et al., 2004).

Most clinicians agree that there is more to their skill than the indiscriminant application of technology. Factors to consider when making the decision regarding initiation or withdrawal of RRT during infancy include quality of life concerns, allocation of resources, legal issues, and, most importantly, the opinions of the hospital team and the parents. Future research into the ethical issues surrounding infant dialysis requires separation of isolated renal failure from renal failure in the setting of comorbid conditions, the cost financially, socially, and emotionally, and research into the informed consent around the initiation of chronic dialysis (Lantos and Warady, 2013). The role of hospital ethics committees in the process remains extremely variable. In the end, clinicians and parents often struggle bravely to reach a compassionate decision with as much agreement as possible. Principles of practice that may provide valuable assistance in this process have been published (Watson, 2004).

Glomerulonephropathies and Disorders of Tubular Function

KELSEY RICHARDSON AND KARYN YONEKAWA

KEY POINTS

- Nephrotic syndrome (NS) is comprised of persistent heavy proteinuria, hypoalbuminemia, edema, and hyperlipidemia.
- Genetic abnormalities of structural or regulatory proteins within the glomerular basement membrane and/or podocyte lead to primary congenital NS (CNS).
- Treatment of CNS does not involve immunosuppression and is aimed at minimizing symptoms and preventing serious complications.
- Infections causing secondary NS include human immunodeficiency virus, syphilis, toxoplasmosis, hepatitis B, malaria, rubella, and cytomegalovirus.
- Renal tubular acidosis (RTA) causes a nonanion gap metabolic acidosis. It is important to evaluate for other sources of bicarbonate (HCO_3^-) loss before initiating a work-up for RTA and to note that immature tubular function in premature infants may cause a self-limited moderate metabolic acidosis in the first 2 weeks of life.
- Inherited renal tubulopathies are rare and can be distinguished from each other in part by differences in serum potassium levels, presence of metabolic acidosis or alkalosis, presence of hypertension, and urine findings (Table 91.1).
- Fanconi syndrome is a condition of diffuse proximal tubule dysfunction resulting in polyuria and wasting of HCO_3^- , amino acids, uric acid, phosphate, glucose, and low-molecular-weight proteins. Fanconi syndrome may be due to an isolated defect or can be a part of a broader genetic syndrome.
- Primary nephrogenic diabetes insipidus may present during pregnancy as polyhydramnios. In the newborn period, treatment should focus on maintaining adequate fluid balance.

Glomerulonephropathies

Generally, glomerulonephropathies are considered when nephrotic syndrome (NS)—the constellation of persistent heavy proteinuria, hypoalbuminemia, edema, and hyperlipidemia—are present. More than 4 mg/kg per hour of protein excretion on a 24-hour urine collection is consistent with nephrotic range proteinuria. Alternately, an untimed “spot” urine protein-to-creatinine ratio can be used when a 24-hour urine collection is impractical. A ratio of 3 mg protein/mg creatinine is consistent with nephrotic range proteinuria.

Congenital Nephrotic Syndrome

Congenital nephrotic syndrome (CNS) is defined as NS onset within the first 3 months of life. Infantile NS refers to NS onset within the first year of life. Both congenital and infantile NS can be divided into primary and secondary causes, with primary being the most common. Genetic abnormalities of structural or regulatory proteins within the glomerular basement membrane and/or podocyte lead to primary CNS (Cil et al., 2015). The podocytes are cells with extensive foot processes that wrap around the capillaries of the glomerulus to prevent loss of proteins from the capillary into the urinary space. Podocytes are anchored in place by many proteins that make up the slit diaphragm, located between podocytes (Fig. 91.1). When there are abnormalities of the podocyte or slit diaphragm proteins, large molecules, such as proteins, may leak into the urinary space leading to proteinuria. Secondary CNS can be a presentation of congenital or perinatal infections or related to underlying metabolic disease (Goldenberg et al., 2005). Diagnosis may be made prenatally when a positive family history is present or because of an elevated amniotic fluid alpha fetoprotein indicating fetal proteinuria. In infants, clinical concerns (e.g., edema, failure to thrive, developmental delay) or NS complications, such as thromboembolism or infection, may lead to work-up and diagnosis (Rheault, 2014). Although most children with CNS require renal transplantation at a young age, there are case reports of CNS with spontaneous resolution or delayed progression, likely related to mild genetic mutations (Wong et al., 2013).

Primary Congenital Nephrotic Syndromes

Finnish-Type Congenital Nephrotic Syndrome (MIM # 256300)

Mutations in the nephrin protein encoding gene *NPHS1* are the most common cause of autosomal recessive (AR) CNS. It is referred to as CNS of the Finnish type (CNF) owing to an incidence of approximately 1 in 8000 live births in the Finnish population (Jalanko, 2009). Nephrin is an essential component of the podocyte slit diaphragm (Hildebrandt, 2010). The classic presentation includes placental enlargement, premature delivery, and proteinuria at birth (Jalanko, 2009). Patients may have microscopic hematuria in addition to massive proteinuria (Fogo et al., 2015). Cardiac abnormalities, such as pulmonary stenosis or patent ductus arteriosus, have been reported in patients with *NPHS1* mutations, although severity and frequency are not well defined (Kari et al., 2014). Renal

TABLE 91.1 Characteristics of Renal Tubular Acidosis Types

| | Inheritance | Acid/Base | Potassium | Other Findings |
|--|---|---------------------|---------------------|--|
| Proximal Tubule | | | | |
| Proximal RTA (type 2) | AD or AR or acquired | Metabolic acidosis | Normal or decreased | |
| Fanconi syndrome (Diffuse proximal RTA) | Inheritance depends on underlying disease or acquired | Metabolic acidosis | Normal or decreased | Aminoaciduria Phosphaturia Glycosuria Uric aciduria Low-molecular-weight-proteinuria |
| Type 4 RTA | Inherited (variable) or acquired | Metabolic acidosis | Increased | |
| Loop of Henle | | | | |
| Barter syndrome | AR | Metabolic alkalosis | Decreased | Hypercalciuria |
| Distal Tubule | | | | |
| Distal RTA (type 1) | AD or AR or acquired | Metabolic acidosis | Normal or decreased | Hypercalciuria |
| Gitelman syndrome | AR | Metabolic alkalosis | Decreased | Hypomagnesemia |
| Gordon syndrome | AD | Metabolic acidosis | Increased | Hypertension Elevated serum aldosterone-to-renin ratio |
| Liddle syndrome | AD | Metabolic alkalosis | Decreased | Hypertension Low serum renin and aldosterone |
| Pseudohypoaldosteronism type 1 | AD or AR | Metabolic acidosis | Increased | Hyponatremia Elevated serum renin and aldosterone |

AD, Autosomal dominant; AR, autosomal recessive; RTA, renal tubular acidosis.

ultrasound images demonstrate large echogenic kidneys with poor corticomedullary differentiation. These imaging findings are similar among all forms of congenital and infantile NS (Jalanko, 2009). Renal biopsy is not always performed, and findings are nonspecific. Electron microscopy demonstrates diffuse foot process effacement (Fogo et al., 2015). The most common light microscopy findings are dilated proximal tubules and microcystic changes, but these are not diagnostic of a *NPHS1* mutation (Machuca et al., 2010).

Congenital Nephrotic Syndrome Type 2 (MIM #600995)

Podocin protein mutations in the *NPHS2* gene lead to the second most common form of AR CNS (Hildebrandt, 2010; Cil et al., 2015). This is the most common gene implicated in CNS in central European populations (Cil et al., 2015). Podocin is essential for targeting nephrin to the slit diaphragm of the podocyte, and protein absence leads to early onset, severe NS (Jalanko, 2009). Clinical presentation is often slightly later than for *NPHS1* mutations, with NS commonly presenting between 4 months and 1 year of age (Boute et al., 2000). Additionally, progression to end-stage renal disease (ESRD) is thought to occur more gradually, with a mean time of 6.6 years from diagnosis to development of ESRD (Hinkes et al., 2007). Ultrasound findings are similar to other forms of congenital and infantile NS. Renal biopsy often shows a pattern consistent with focal segmental glomerular sclerosis (Fogo et al., 2015).

Wilms Tumor Suppressor Gene Mutation Syndromes (MIM #194072, 136680, 194080)

Mutations of the Wilms tumor suppressor gene (*WT1*) may result in isolated diffuse mesangial sclerosis or be part of a syndrome associated with CNS such as Wilms tumor, aniridia, genitourinary abnormalities, and intellectual disabilities (WAGR), Frasier, or

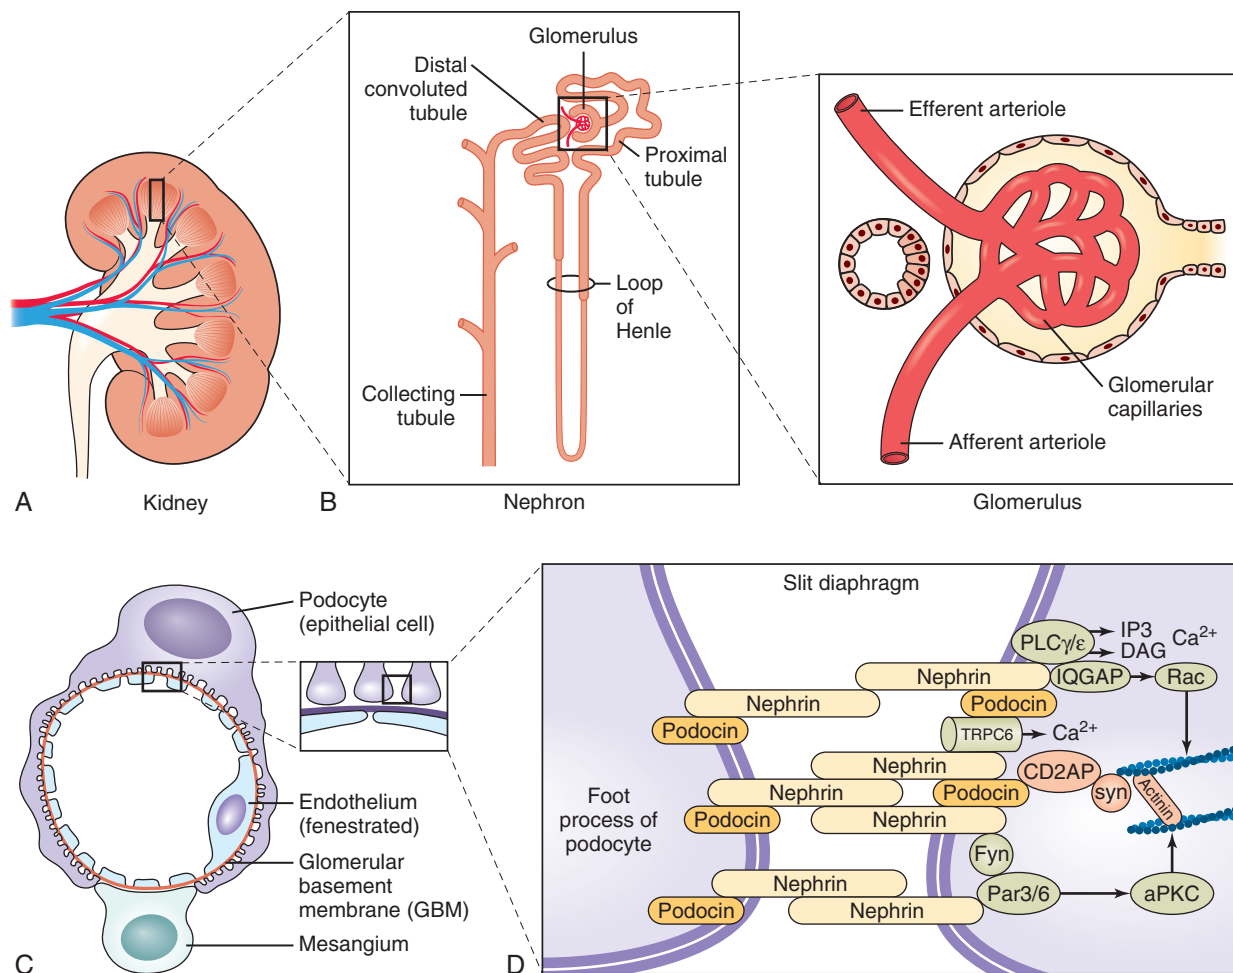

Denys–Drash syndrome. On average, ESRD occurs at 3 years of age but can occur in infancy, and disease severity is partially dependent on mutation type. Patients with *WT1* mutations are at risk for Wilms tumors and gonadoblastomas and should be screened for these malignancies. Patients should also be screened with karyotype testing and, possibly, further genitourinary imaging, as they may have ambiguous genitalia or other genitourinary tract anomalies such as cryptorchidism in males or uterine abnormalities in females (Lipska et al., 2014). The histologic findings on renal biopsy demonstrate either diffuse mesangial sclerosis, identified by mesangial collagen increase on light microscopy, or focal segmental glomerular sclerosis (FSGS) (Lipska et al., 2014; Fogo et al., 2015).

Pierson Syndrome (MIM #609049)

Pierson syndrome is an AR disorder caused by mutations in *LAMB2*, which codes for the beta 2 chain of laminin, a basement membrane protein. Children classically present with NS and microcoria (small pupils with inability to dilate). As laminin is present in multiple basement membrane structures throughout the body, patients may also have hypotonia, developmental delay, or other vision deficits (Wuhl et al., 2007). Age of presentation varies depending on the mutation type, but many present in the first year of life. Renal biopsies in these children most commonly show features of diffuse mesangial sclerosis with irregular lamellation seen on electron microscopy (Choi et al., 2008; Machuca et al., 2010).

Other Primary Causes of Congenital Nephrotic Syndrome (MIM #251300, 161200)

Galloway–Mowat syndrome is a rare AR condition in patients with NS and central nervous system anomalies, primarily microcephaly, with a genetic defect in the *WDR73* gene (Dietrich et al.,

• **Fig. 91.1** (A) The kidney contains approximately one million nephrons. (B) The nephron is composed of a glomerulus, proximal tubule, loop of Henle, distal tubule, and collecting duct. (C) The glomerular filtration barrier is composed of fenestrated endothelial cells, a basement membrane, and epithelial cells (podocytes). (D) Podocytes have structures called foot processes. The area between the foot processes is called the slit diaphragm. Proteins such as nephrin and podocin are essential for proper functioning of the slit diaphragm and filtration barrier. *actinin*, α -actinin-4; *aPKC*, atypical protein kinase C; *CD2AP*, CD2 adaptor protein; *DAG*, diacylglycerol; *IP3*, inositol 1,4,5 triphosphate; *IQGAP*, IQ motif containing GTPase activating protein 1; *PLC*, phospholipase C; *syn*, synaptopodin; *TRPC6*, transient receptor potential-like channel 6. (Adapted from Chiang CK, Inagi R. Glomerular diseases: genetic causes and future therapeutics. *Nat Rev Nephrol.* 2010;6:539–554.)

2008). Nail–patella syndrome is an autosomal dominant (AD) condition associated with *LMX1B* mutations leading to proteinuria, nail dysplasia, glaucoma, and bony anomalies classically identified by the presence of iliac horns (Bongers et al., 2002). This syndrome usually does not result in NS in infancy but may present early in life with proteinuria or bony abnormalities. *Lamb3* mutations have been found in individuals with NS and epidermolysis bullosa (Dietrich et al., 2008).

Management of Primary Congenital Nephrotic Syndromes

Primary CNS does not respond to the immunosuppressive treatments used for idiopathic NS. Given the abnormal or absent functional proteins in the basement membrane or slit diaphragm, this group of diseases is generally treated with symptomatic management targeted at minimizing protein loss. Definitive treatment is renal transplantation, but supportive therapies are used until the

child is of appropriate age and size for renal transplantation. The basic principles of management include maintenance of intravascular volume, minimization of proteinuria, adequate nutritional support, and maintaining electrolyte balance.

Albumin infusions are given to replace protein loss and restore intravascular volume. Diuretics are used in combination with intravenous albumin infusions to avoid severe edema. Treatment frequency varies based on patient characteristics. Medications to decrease the glomerular filtration rate by modulating renal blood flow can be used in an attempt to limit protein loss. Angiotensin-converting enzyme inhibitors and nonsteroidal antiinflammatory drugs (NSAIDs) can be used for this purpose either alone or in combination (Licht et al., 2000; Kovacevic et al., 2003). If medication management is insufficient to maintain stable serum albumin concentrations and prevent severe edema, then nephrectomy, unilateral or bilateral, would be indicated.

Actively nephrotic children are at risk for many serious complications and should be monitored vigilantly. Protein loss is not specific as the podocyte lesion allows varied protein sizes into the urine. Immunoglobulins, coagulation proteins, thyroid binding proteins, and other proteins are lost in the urine. Approximately 10% of children will experience thrombotic complications, and the majority will experience serious bacterial infections (Kim et al., 1998). All children will experience failure to thrive without nutritional supplementation, which often requires tube feedings. Management with intravenous immunoglobulins (IVIGs) is not routinely recommended because of the rapid loss of the IVIG proteins into the urine (Payne et al., 2013). No standard guidelines exist regarding when nephrotic children should receive anticoagulation. However, hypercoagulability is of particular concern in children requiring central venous access, and this subgroup should be placed on antithrombotic therapy. Hypothyroidism is common due to thyroid binding protein loss in the urine. Smaller studies report refractory anemia related to transferrin and transcobalamin loss (Toubiana et al., 2009). Ceruloplasmin loss in the urine leading to copper deficiency has been reported, causing neutropenia and refractory anemia (Ulinski et al., 2009).

Most children progress to renal transplantation. At present, patients with CNS are expected to do as well as children with ERSD due to other etiologies (Jalanko, 2009). A small percentage of patients, particularly with CNF, do have a return of proteinuria after transplantation because of antibody formation against the previously absent nephrin protein (Mejía et al., 2015).

Secondary Causes of Congenital Nephrotic Syndrome

Although primary forms of CNS are most common, clinicians should consider secondary causes in children with negative genetic testing or clinical findings that point to other etiologies. For example, children with signs of metabolic disease in addition to their proteinuria should be evaluated for mitochondrial cytopathies. Those with nipple inversion and other dysmorphisms should be evaluated for congenital disorders of glycosylation (Park et al., 2015). Congenital and perinatal infections may cause CNS, a finding more common in developing countries. Implicated infections include human immunodeficiency virus, syphilis, toxoplasmosis, hepatitis B, malaria, rubella, and cytomegalovirus. Infection-related NS may respond with appropriate antimicrobial treatment, depending on the degree of glomerular damage.

Other Glomerular Diseases

Neonatal glomerulonephritis (GN) is uncommon and primarily described in case reports. GN is defined by proteinuria and hematuria accompanied by varying degrees of acute kidney injury, oliguria, and hypertension. Rarely, maternal antibody transfer can lead to membranous nephropathy in a neonate because of absence of maternal neutral endopeptidase and subsequent antibody production following exposure to fetal neutral endopeptidase. The infant may experience transient glomerulopathy or may develop chronic kidney disease (Debiec et al., 2004). Additionally, nephritis may be the result of transfer of maternal antibodies related to systemic lupus erythematosus to the infant (Rheault, 2014).

Renal Tubular Disorders

The renal tubule regulates and modifies the glomerular filtrate to avoid excess salt and water loss in the urine. Defects along the tubule lead to varying pathology. The proximal tubule is in charge

of bulk water and electrolyte reabsorption. The distal nephron delicately regulates the final urinary product with close regulation of acid–base balance and water reabsorption. In neonates, genetic causes of tubular dysfunction predominate; however, medications and other secondary causes of tubular dysfunction can occur. Adequate evaluation of renal tubular disorders in neonates can be complicated by the use of intravenous fluids, parenteral nutrition, or electrolyte supplementation, as these modify the serum and urine studies. In addition, the renal tubules of premature infants continue to mature after birth, particularly with improved sodium reabsorption over the first month of life (Gubhaju et al., 2014). This immature tubular function may cause a self-limited moderate metabolic acidosis in the first 2 weeks of life (Bourchier and Weston, 2015).

Renal Tubular Acidosis

Renal tubular acidosis (RTA) is suspected in children with a nonanion gap hyperchloremic metabolic acidosis. Type 1 RTA is due to a distal nephron defect, type 2 is due to a proximal tubule defect, type 3 is a mix of type 1 and type 2 defects, and type 4 is due to hypoaldosteronism or aldosterone resistance.

Children with RTA present with failure to thrive, emesis, and polyuria. It is important to evaluate for other sources of bicarbonate (HCO_3^-) loss, such as diarrhea, as this should be addressed before pursuing a work-up for RTA. Baseline testing of serum electrolytes, blood gases, and a urine sample should be obtained while the child is acidotic. Calculation of a serum anion gap is helpful to determine if a high anion gap acidosis or a normal anion gap acidosis is present, as RTA is associated with a normal anion gap acidosis. The anion gap is a calculation of serum cations minus serum anions. A high anion gap usually indicates increased unmeasured anions, whereas a normal anion gap acidosis is usually due to increased serum chloride. The anion gap is calculated from serum chemistries ($[\text{sodium } \{\text{Na}^+\}] - ([\text{chloride } \{\text{Cl}^-\}] + [\text{HCO}_3^-])$), and normal values are between 7 and 13 milliequivalent (mEq)/L. Of note, sometimes potassium (K^+) is used in the equation, which increases the normal range to 11–14 mEq/L. The presence of an anion gap acidosis should lead clinicians away from the diagnosis of RTA. Urinary studies will help differentiate between the types of RTA. The urinary anion gap is used to approximate urinary ammonium (NH_4^+) concentration, and it is calculated by $(\text{U}_{\text{Na}^+} + \text{U}_{\text{K}^+} - \text{U}_{\text{Cl}^-})$. Urine anion gap is negative in the setting of high urinary NH_4^+ concentration, as NH_4^+ excretion leads to increased chloride anion excretion, and the excess chloride is measured in the urinary anion gap. The urinary anion gap is positive with inadequate NH_4^+ concentration in the urine; however, in the setting of volume depletion and low urine sodium (≤ 25 mmol/L) the urine anion gap is also positive as the kidney reabsorbs chloride and has limited ammonia excretion (Sulyok and Guignard, 1990; Kim, 2011). This volume depletion setting may mimic the serum and urine anion gap findings of RTA. Urinary osmolar gap $(\text{U}_{\text{Osm}} - 2\text{U}_{\text{Na}^+} + 2\text{U}_{\text{K}^+} + (\text{U}_{\text{urea}} (\text{mg/dL})/2.8) + \text{U}_{\text{glucose}} (\text{mg/dL})/18)$ also helps determine if adequate NH_4^+ excretion is present. An elevated urinary osmolar gap (>1000 mOsm/kg) suggests high NH_4^+ excretion (Kraut and Madias, 2012).

Fanconi Syndrome

Fanconi syndrome is a condition of diffuse proximal tubule dysfunction. Children with Fanconi syndrome have polyuria and wasting of HCO_3^- , amino acids, uric acid, phosphate, glucose, and low-molecular-weight proteins. Fanconi syndrome may be an isolated defect or part of a broader genetic syndrome.

Nephropathic Cystinosis (MIM #219800)

Cystinosis is the most common cause of primary proximal tubular dysfunction in children. It is an AR lysosomal storage disease caused by a defect in the transporter cystinosin. This protein is responsible for cystine transport through the lysosome, and mutations cause cystine accumulation within the proximal tubular cells and throughout the body. The renal manifestations of cystinosis present early in life and often lead to diagnosis of the disease (Emma et al., 2014). Additional clinical features include corneal deposits, hepatomegaly, insulin dependent diabetes mellitus, weakness, infertility, and hypogonadism. Corneal deposits initially cause light sensitivity and later lead to significant visual impairment.

Cystinosis diagnosis is made by measuring leukocyte cysteine levels, detecting corneal deposits, or genetic testing. Genetic testing can also be done prenatally by chorionic villi sampling (Jackson and Young, 2005). Discovery of cysteamine in 1976, now the mainstay of treatment, was a breakthrough in the treatment of patients with cystinosis (Goodyer, 2011). Cysteamine decreases cystine concentration within cells, and although cysteamine therapy cannot reverse renal tubular dysfunction, it can help preserve glomerular filtration rate, delaying the onset of ESRD (Nesterova et al., 2015). Measurement of leukocyte cystine depletion is used to monitor efficacy of therapy. Compliance with treatment is difficult as the medication has many side effects such as gastrointestinal upset, bad breath, body odor, and skin lesions at high doses. Additionally, it requires dosing multiple times per day, depending on the formulation. Cysteamine eye drops are used to limit corneal deposits, and these require hourly dosing.

Other Causes of Fanconi Syndrome

Tyrosinemia (MIM #276700) and classic galactosemia (MIM #230400) are both part of the uniform newborn screening panel performed in the United States. Therefore they are often diagnosed early in life. Tyrosinemia is an AR disorder where toxic metabolites accumulate in the liver and kidney. Early therapy with nitisinone to reduce the production of toxic metabolites can improve renal proximal tubular dysfunction (Maiorana et al., 2014). Classic galactosemia is also AR and presents early in life with emesis, lethargy, hepatomegaly, sepsis, and failure to thrive. Cataracts may also be present in infancy. Proximal tubular dysfunction can accompany galactosemia and exacerbate the clinical picture, although dietary modification can prevent worsening of tubular dysfunction (Bosch, 2006).

Hereditary fructose intolerance (MIM #229600) does not usually present until fructose or sucrose is added to an infant's diet. Infants present with emesis and hypoglycemia and on subsequent evaluation may be found to have proximal tubular dysfunction due to deficient aldolase B within the kidney. Early dietary modification can prevent renal complications (Ali et al., 1998).

Lowe syndrome (MIM #309000), also known as the oculocerebrorenal syndrome, is a rare X-linked syndrome. Congenital cataracts and hypotonia are often detected at birth, with proximal tubulopathy developing over subsequent weeks to months (Loi, 2006).

Dent disease (MIM #300009) is another rare X-linked recessive proximal tubulopathy. It is characterized by hypercalciuria and recurrent nephrolithiasis. Urinary phosphate losses can lead to rickets and significant bone abnormalities in infancy (Devuyst and Thakker, 2010).

Fanconi syndrome is also a defining feature of Fanconi-Bickel syndrome (MIM #227810), which is characterized by hepatic and

renal dysfunction caused by *GLUT2* mutations (Bockenhauer and Bichet, 2015). This generally presents after a few months of life but can be seen in early infancy.

In addition to the variety of genetic syndromes described above, many medications can lead to a proximal tubular dysfunction. Common offending medications include tenofovir, ifosfamide, carbonic anhydrase inhibitors, and aminoglycosides.

Isolated Proximal Renal Tubular Acidosis (Type 2 RTA)

Proximal RTA is not often seen in isolation and usually accompanies the more diffuse proximal tubular dysfunction, Fanconi syndrome, described earlier. The proximal tubule generally reabsorbs 80% of filtered HCO_3^- ; therefore defects lead to massive bicarbonaturia and subsequent acidosis. Serum potassium may be normal or decreased, due to impaired proximal potassium reabsorption in the setting of metabolic acidosis.

Inherited isolated proximal RTA is rare. It can be associated with ocular abnormalities and mental retardation (Santos et al., 2015). Age of presentation is variable. Proximal RTA can be distinguished from distal RTA by the absence of hypercalciuria and absence of nephrocalcinosis. In proximal RTA, the urinary pH is often inappropriately high (>5.5) due to bicarbonaturia; however, once the serum HCO_3^- drops, less HCO_3^- will be filtered at the glomerulus, and urinary pH will also drop (<5.5). Treatment is with alkali replacement to correct the metabolic acidosis; however, large doses of HCO_3^- supplementation are often needed to maintain balance. As this therapy can often worsen hypokalemia, potassium supplementation is also needed.

Distal Renal Tubular Acidosis (Type 1 RTA)

Distal RTA is caused by an inability of the collecting duct to excrete adequate hydrogen (H^+) ions because of poor NH_4^+ excretion. Inherited distal RTA typically presents early in life with hyperchloremic metabolic acidosis, failure to thrive, hypercalciuria, and nephrocalcinosis that is usually seen on ultrasound within the first month of life (Santos et al., 2015). Patients may be hypokalemic due to decreased distal hydrogen ion secretion and subsequent increased distal potassium excretion to maintain electroneutrality within the urinary filtrate. Specific AR mutations in the H^+ adenosine triphosphatase have been associated with sensorineural hearing loss as well as distal RTA (Vargas-Poussou et al., 2006). Individuals with distal RTA typically have an inappropriately high urinary pH, generally greater than 5.5. The urine anion gap is usually positive, and the urine osmolar gap is low, representing inadequate NH_4^+ excretion. Treatment is with alkali supplementation.

Hyperkalemic Tubulopathies (Type 4 RTA)

Hypoaldosteronism

Clinical hypoaldosteronism may be due to either a deficiency in aldosterone production or an inability of the renal tubules to respond to aldosterone (pseudohypoaldosteronism). Aldosterone deficiency can be primary in cases of congenital adrenal insufficiency or secondary due to drugs or infection and is outside the scope of this chapter.

Pseudohypoaldosteronism Type 1

Pseudohypoaldosteronism type 1 can be AD or AR and involves a loss of function mutation of the ENaC channel. This can present in infancy with volume depletion, hyponatremia, hyperkalemia, and acidosis. Because of mineralocorticoid resistance, patients have symptoms and laboratory results consistent with hypoaldosteronism

but with elevated renin and aldosterone levels. Management requires treatment with Na^+ supplementation and K^+ restriction.

Gordon Syndrome (Pseudohypoaldosteronism Type 2)

Gordon syndrome is an AD hypertensive condition that traditionally presents at an older age with hyperkalemia and metabolic acidosis. Hypertension is due to volume overload through mutations in the distal convoluted tubule that increase Na^+ and Cl^- reabsorption. Although renin levels are depressed, aldosterone is not suppressed and therefore the aldosterone-to-renin ratio is elevated, which can help in the diagnosis. Low-dose diuretics are the mainstay of therapy (Simonetti et al., 2012).

Hypokalemic Tubulopathies

Bartter Syndrome (MIM #601678, 241200, 607364, 613090, 602522, 601198)

Bartter syndrome is caused by AR mutations in the thick ascending limb (TAL) of the loop of Henle. There are many known types of Bartter syndrome. To date, mutations in the genes *SLC12A1*, *KCNJ1*, *CLCNKB*, *CLCNKA*, *BSND*, and *CASR*, have been found. Bartter syndrome is extremely rare, with a prevalence of 1 in 1,000,000 based on adult studies (Ji et al., 2008). Bartter syndrome often comes to clinical attention based on poor growth and development, typically at a young age. Impairment of sodium chloride reabsorption in the TAL leads to decreased urinary concentrating ability, polyuria, volume depletion, and renin and aldosterone system activation. The secondary aldosterone activation increases Na^+ reabsorption and K^+ and H^+ ion excretion. This physiology can be thought of as analogous to the effect seen with loop diuretics.

Laboratory evaluation will demonstrate hypokalemia, metabolic alkalosis, hypochloremia, and hypercalciuria. Serum magnesium is often normal. Nephrocalcinosis may develop in infancy because of high urinary calcium. Sometimes, differentiation of Bartter syndrome from electrolyte abnormalities related to volume depletion can be difficult. Urinary Cl^- measurement can be very useful, as this should be low (<35 mEq/L) in patients with volume depletion (Veldhuis et al., 1979). Bartter syndrome patients uniquely have elevated urinary Cl^- in the presence of hypochloremia.

Bartter syndrome type IV is uniquely associated with sensorineural hearing loss, as the barttin protein is present in the kidney and the inner ear (Landau et al., 1995). Genetic testing can confirm the diagnosis and specific mutation type; however, the diagnosis is primarily made clinically. Types I, II, and IV may be detected prenatally as part of the work-up for polyhydramnios. Amniotic fluid alpha fetoprotein should be low in cases of suspected Bartter syndrome (Allaf et al., 2015).

Early fluid management is with adequate volume and electrolyte repletion, necessary to allow appropriate growth (Azzi et al., 2015). The TAL defect leads to an upregulation of prostaglandin- E_2 , therefore NSAIDs can help counteract this problem and limit fluid and electrolyte losses. Spironolactone and amiloride may also be used to limit distal potassium loss and minimize the need for large-dose potassium supplements.

There has recently been a new mutation described in melanoma-associated antigen D2 (*MAGE-D2*) on the X chromosome, which leads to a severe but transient form of neonatal Bartter syndrome. This mutation has been associated with perinatal death (Laghmani et al., 2016). These patients have an earlier, more severe presentation with polyhydramnios around the 20th week of gestation. Because of massive polyhydramnios, infants are often born premature. In

the small group of infants studied, polyuria resolved at a median of 4.5 weeks after birth (Laghmani et al., 2016).

Gitelman Syndrome (MIM #263800)

Gitelman syndrome is AR with defects found in the *SLC12A3* gene, which codes for the sodium chloride cotransporter in the distal convoluted tubule. Gitelman syndrome presents with hypokalemia and metabolic alkalosis similar to Bartter syndrome. However, in contrast to Bartter syndrome, it typically presents later in life and with hypomagnesemia and hypocalciuria. This condition can be thought of as analogous to the laboratory findings seen in patients being treated with a thiazide diuretic. Patients commonly present with muscle weakness, paresthesia, paralysis, or tetany. Diagnosis is primarily made based on serum and urine electrolyte measurements and can be confirmed with genetic testing. Treatment involves NSAIDs and drugs that block distal potassium-sodium exchange, combined with potassium and magnesium supplementation.

Liddle Syndrome (MIM #177200)

Liddle syndrome is an AD condition where children are hypertensive because of a distal tubule gain of function mutation in epithelial sodium channel (ENaC). A mutation in this channel, which is responsible for distal sodium reabsorption, leads to excess sodium and subsequent water reabsorption. Consequently, Liddle syndrome is associated with low renin and aldosterone levels, and, classically, hypokalemia and metabolic alkalosis accompany this disease. Triamterene is the therapy of choice as it directly inhibits ENaC channels (Simonetti et al., 2012). Low sodium diet is also beneficial in minimizing the effects of ENaC activation.

Other Tubulopathies

Nephrogenic Diabetes Insipidus (MIM # 304800, 125800)

In children, nephrogenic diabetes insipidus (NDI) is more often primary than secondary. Arginine vasopressin receptor type 2 (*AVPR2*) mutations are inherited in an X-linked recessive pattern and are the most common genetic defect, accounting for 90% of primary NDI (Wesche et al., 2012). Typically, arginine vasopressin is released from the pituitary in response to volume depletion and signals increased water reabsorption. *AVPR2* encodes for arginine vasopressin receptor-2, the receptor for arginine vasopressin on the basolateral surface of collecting duct cells. Receptor activation leads to translocation of aquaporin channels to the apical surface of the nephron for water reabsorption. Mutations in *AVPR2* result in arginine vasopressin resistance because of an inability to appropriately interact with circulating vasopressin (Bockenhauer and Bichet, 2015). Defects in the aquaporin channel are inherited in an AR pattern and are much less common (Wesche et al., 2012).

Children with genetic forms of NDI present at a young age with polyuria, failure to thrive, and hypernatremic volume depletion. Infants and small children that do not have the ability to increase their own water intake based on thirst responses are at greatest risk of complications, particularly at times of illness. Long-term complications include developmental delay, growth failure, and chronic kidney disease, all thought to be secondary to repeated volume and Na^+ depletion and rapid fluid shifts. Prenatal polyhydramnios may be appreciated during pregnancy.

Imaging often demonstrates a dilated urinary system because of the high volumes of urine. Elevated arginine vasopressin hormone levels in the setting of hypernatremic volume depletion and polyuria can help differentiate central diabetes insipidus from NDI, as can a

desmopressin challenge. Definitive diagnosis is made through genetic testing.

Treatment focuses on providing adequate fluids in the newborn period. Decreasing the osmolality of the infant's formula helps maintain balance as these children have a limited ability to excrete osmotic loads. Higher osmolality necessitates increased urine volume. Since the osmotic and salt load of breast milk are much lower than cow milk-based formula, breastfed infants often present later than formula-fed infants (Wesche et al., 2012). Thiazide diuretics and nonsteroidal prostaglandin-synthetase inhibitors aid in management. Thiazide diuretics block sodium chloride reabsorption in the distal tubule leading to mild volume depletion, stimulating upregulation of proximal tubular sodium and water reabsorption to overcome some of the massive water loss in the distal nephron. The mechanism of how nonsteroidal prostaglandin-synthetase inhibitors decrease polyuria is not well understood, but they are particularly effective when combined with a thiazide diuretic. Gastrointestinal upset may limit usage however (Pattaragarn and Alon, 2003). Recently, sildenafil has been presented as a possible treatment to reduce proteinuria in therapy-resistant patients (Assadi and Sharbaf, 2015). These current therapies are primarily aimed at symptomatic relief, but new research is investigating protein folding and increased protein expression, to better target the cause of disease (Wesche et al., 2012).

Urinary Tract Infections and Vesicoureteral Reflux

PETER (ZHAN TAO) WANG, ORCHID DJAHANGIRIAN, AND ELIAS WEHBI

KEY POINTS

- The presentation of urinary tract infections (UTIs) in neonates differs from that seen in older children.
- The type and route of infection also differ in neonates, when compared with older children.
- An appropriate urine sample for diagnosis is needed, but treatment should not be delayed.
- A neonate in whom a UTI is suspected should be evaluated for sepsis, including invasive cultures.
- After a documented neonatal UTI, a radiologic work-up is warranted to detect anatomic anomalies.
- Vesicoureteral reflux (VUR) is diagnosed in 30%–50% of neonates with proven UTI.
- Voiding cystourethrogram is the gold standard for the diagnosis of VUR and should be performed on high-risk neonates.
- Treatment of VUR should be tailored to each patient's individual risk of UTI recurrence, with the goals of preventing future UTIs and renal scar formation.

Urinary Tract Infection

Urinary tract infections (UTIs) in the newborn period are common and differ in their epidemiology, risk factors, presentation, treatment, and prognosis compared with those of older infants and children. This chapter will discuss UTIs in neonates, with an emphasis on vesicoureteral reflux (VUR).

Epidemiology

Neonates, by virtue of their immature immune system, are at a higher risk for UTIs (Hanson, 1976). In the United States the incidence of UTI within the first 3 days of life is estimated at 0%–1% (Morley et al., 2012; Bonadio and Maida, 2014), while in developing countries it is as high as 1.8% (Samayam and Ravi Chander, 2012; Riskin et al., 2013). UTI is the second most common bacterial infection in children after otitis media (Bachur and Harper, 2001).

In febrile children less than 2 months of age without an obvious source of infection, the prevalence of UTI is 5%–20% (Hoberman et al., 1993; Giorgi et al., 2005; Shaikh et al., 2008). There is a

male predominance in the neonatal period, with males comprising 70%–90% of all cases of neonatal UTI before the age of 6 months (El-Dahr and Lewy, 1992; Wang et al., 1994; Kanellopoulos et al., 2006) irrespective of their degree of prematurity (Eliakim et al., 1997). Hispanics and whites are more likely to be diagnosed with a UTI than children of African descent (Airede, 1992; Chen and Baker, 2006).

Pathophysiology

The natural pathophysiology of UTI is dependent on the migration of uropathogenic bacteria through the fecal–perineal–urethral route (Gruneberg, 1969; Yamamoto et al., 1997) with subsequent entry into the bladder. Iatrogenic instrumentation and hematogenous seeding are alternative modes of entry into the urinary system. Once in the bladder, these uropathogens may ascend into the ureter and kidney in a retrograde manner. The effectiveness of this process is determined by both pathogen and host factors.

Host factors in the neonate often relate to anatomy and involve urogenital malformations such as posterior urethral valves, VUR, phimosis, ureteropelvic junction obstruction, and neurogenic bladder dysfunction secondary to spinal dysraphism. These conditions ultimately disturb the washout effect of antegrade urinary flow that would normally clear the uropathogens (Cox and Hinman, 1961). Additional host factors include neonatal immune function and the antimicrobial properties of urine such as low pH (Sobel, 1997).

Uropathogens have a number of virulence factors that are used to overcome the defense of the host. *Escherichia coli* serotypes with P-fimbriae are commonly isolated in infected urine (Johnson, 2003). These are adhesion proteins at the tip of the bacterium's attachment structures that enhance binding to receptors on the host urothelium (Sussman and Gally, 1999; Wullt et al., 2000; Bower et al., 2005). These increase the bacteria's ability to ascend the urinary tract, even in the absence of VUR (Pohl, 2007).

Epidemiologic studies have shown that 76%–94% of pyelonephritic strains of *E. coli* are P-fimbriated, compared with 19%–23% of strains causing cystitis and 14%–18% of strains isolated from patients with asymptomatic bacteriuria (Vaisanen-Rhen et al., 1984; Tomisawa et al., 1989). However, in the presence of VUR, P-fimbriated *E. coli* is not necessary for infection of the upper tracts. In one study, P-fimbriated *E. coli* was isolated in only 36% of girls with VUR and recurrent pyelonephritis, as compared with

71% of girls with pyelonephritis without VUR (Lomberg et al., 1989).

Other virulence factors from uropathogenic *E. coli* include the release of alpha hemolysin and cytotoxic necrotizing factor-1 (Uhlen et al., 2000; Guyer et al., 2002; Toth et al., 2003), as well as the ability to form a protective glycosylated polysaccharide capsule (Russo et al., 1996).

Presentation

The signs and symptoms of UTI in newborns differ from those of their older counterparts. The familiar symptoms of dysuria, frequency, urgency, malodorous urine, incontinence, suprapubic pain, and hematuria are often absent or not recognized. The clinician must retain a high index of suspicion for the diagnosis of a UTI in a neonate. In full-term infants the most common presentation is a fever of greater than 38.5°C (Littlewood, 1972; Kanellopoulos et al., 2006) followed by poor feeding, tachypnea, and lethargy. In contrast, premature infants commonly present with apnea, hypoxia or tachypnea, and fevers with a temperature greater than 39°C (Milas et al., 2013). Other nonspecific signs and symptoms, such as abdominal distention, diarrhea, vomiting, and failure to thrive, have also been described in infants with a UTI (Arshad and Seed, 2015).

Neonatal jaundice, especially with an onset after 8 days of life, has been associated with neonatal UTIs (Garcia and Nager, 2002; Milas et al., 2013). Mutlu et al. (2014) found that the incidence of UTI in children with hyperbilirubinemia was 18%. This is an important association, as Xinias et al. (2009) showed that approximately 50% of neonates with UTI-induced jaundice had renal cortical changes on dimercaptosuccinic (DMSA) scan.

Bacteriology

Neonatal UTIs are commonly caused by gram-negative rods, with *E. coli* (40%–72%) and *Klebsiella* species (7%–40%) responsible for over 80% of cases (Chen et al., 2011; Shahian et al., 2012). Enterococcus, a gram-positive coccus, is the third most common organism, with an incidence of 10%–16% (Bonadio and Maida, 2014; Arshad and Seed, 2015).

In neonates with UTIs, group B streptococci have been found to be more common than in older children (Wu et al., 2004). Additionally, other gram-positive bacteria, such as coagulase-negative staphylococci, have been associated with UTIs in premature infants, although this remains controversial (Jean-Baptiste et al., 2011). Candida, as a causative agent for UTIs, has a reported incidence of 25%–42% in premature children admitted to the neonatal intensive care unit (Phillips and Karlowicz, 1997; Benjamin et al., 2010).

Risk Factors

The risk factors for UTIs in neonates are circumcision status in males, a maternal history of UTI, and anatomic anomalies.

The decreased risk for UTI in circumcised males is supported by two metaanalyses, conducted by Singh-Grewal et al. (2005) and Shaikh et al. (2008). In febrile neonates the incidence of UTI in uncircumcised males is 20%–21% compared with 2% in circumcised males and 5%–8% for females (Zorc et al., 2005; Shaikh et al., 2008). This phenomenon is supported by studies showing a higher concentration of uropathogenic bacteria in the periurethral region of uncircumcised males (Wiswell et al., 1988).

Laway et al. (2012) prospectively studied the effects of circumcision on the colonization of the periurethral area of 124 children. The authors found that the periurethral region was devoid of *E. coli*, klebsiella, proteus, pseudomonas, and enterococci after the children underwent circumcision, whereas these uropathogenic bacteria were present in 68% preoperatively. The American Academy of Pediatrics (AAP) currently does not support the recommendation of routine neonatal circumcisions, following its review of the current scientific literature (Sorokan et al., 2015). Despite this, the authors believe that circumcision or treatment of phimosis in high-risk children, such as those with high-grade VUR or those with posterior urethral valves, may be of benefit.

A maternal history of UTI is a risk factor for neonatal UTI. Milas et al. (2013) studied 1200 newborns for a 6-month period and showed that neonates with UTIs were more likely to have mothers that were diagnosed with a UTI during the pregnancy (22.2% vs 5.2%, $P < .001$). This was further supported by a cross-sectional study by Khalesi et al. (2014) who demonstrated a 5.9-fold increased risk for neonatal UTI in newborns where there was a history of maternal UTIs.

The overall reported incidence of genitourinary abnormalities in neonates is 5% (Bonadio and Maida, 2014). VUR is a common renal abnormality predisposing neonates to UTIs and pyelonephritis. Cleper et al. (2004) retrospectively studied 64 neonates with UTIs and found the incidence of VUR to be 20.3%, of which 31% represented high-grade VUR. However, other studies have reported rates between 20%–50% (White, 1989; Gerard et al., 1998). In male neonates with UTI, the most common anomaly was VUR (Goldman et al., 2000). In neonates with UTI the incidence of VUR increases to 30%–50% (Ginsburg and McCracken, 1982; Bonadio and Maida, 2014). Although other anatomic abnormalities, such as posterior urethral valves, congenital urethral strictures, ureteroceles, ureteropelvic junction obstruction, and neurologic bladder dysfunction, increase the risk of UTIs, these are less common than VUR. An obstructive pathology represents less than 1%–2% of the abnormalities found in neonates with UTIs (Hoberman and Wald, 1997). As such, the discussion of this chapter will focus on VUR.

VUR is defined as the retrograde flow of urine from the bladder to the upper urinary tract. Primary VUR is thought to result from the abnormal structure and function of the ureterovesical junction, whereas secondary VUR is acquired as a result of increased intravesical pressure. Normally the ureters enter the bladder obliquely, where a certain length of the ureter courses intramurally and submucosally. This creates a flap-valve mechanism where the distal ureter is compressed as the bladder fills with urine, thus normally preventing urine backflow. Fig. 92.1 demonstrates this relationship.

The lateral displacement of the ureteric orifice in the bladder in patients with VUR is thought to occur as a result of an abnormal ureteric bud origin along the mesonephric duct, where the extent of lateral displacement correlates with the degree of associated renal dysplasia (Mackie and Stephens, 1975). The International Reflux Study grading system is the most commonly accepted (Committee, 1981). Fig. 92.2 describes the appearance of each grade along with an example of each on voiding cystourethrogram (VCUG).

The bacterial etiology in neonates with VUR is distinct, with the presence of species such as *Proteus mirabilis*, *Proteus vulgaris*, *Pseudomonas aeruginosa*, and *Morganella morganii* (Zorc et al., 2005; Kanellopoulos et al., 2006). In addition, *Klebsiella pneumoniae* has a higher incidence in neonates with VUR presenting

• **Fig. 92.1** Normal Course of the Ureter in the Bladder. Notice how the ureter courses through the bladder wall (intramural portion) and under the mucosa (submucosal portion) to expel urine into the bladder through the ureteric orifice.

with a UTI compared with those without VUR (Cleper et al., 2004).

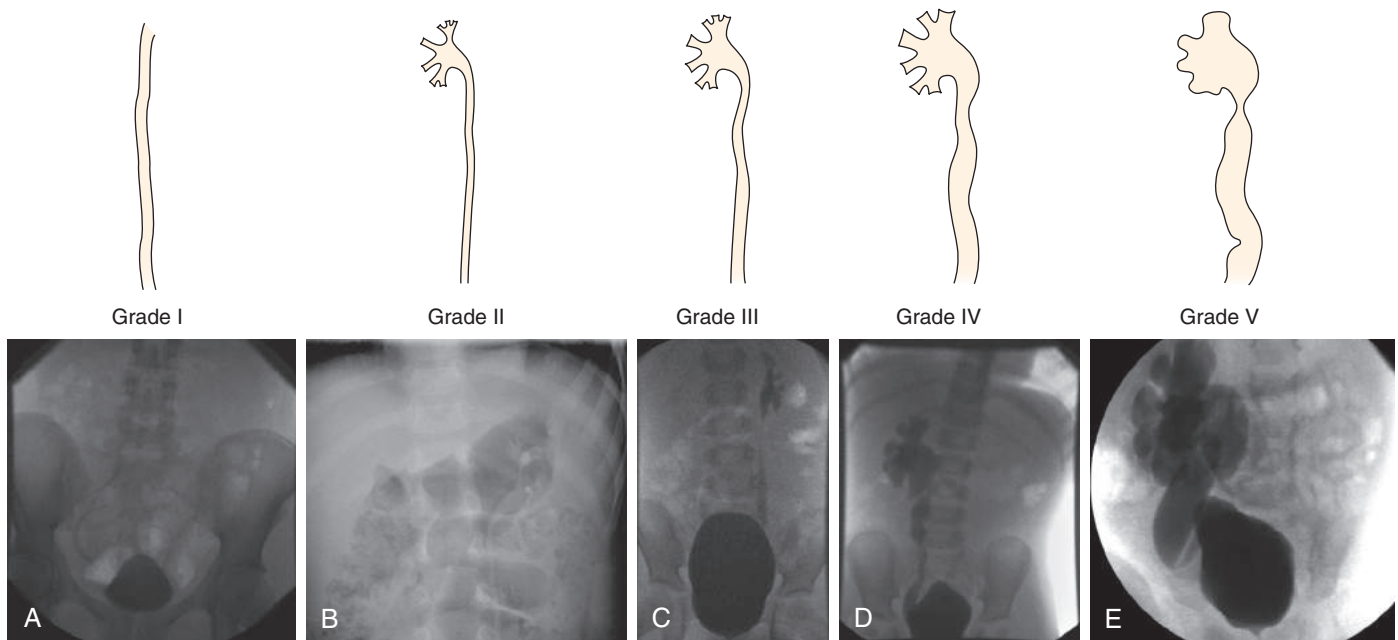

Diagnosis

The diagnosis of UTI in neonates differs from older children. An initial assessment should involve a detailed history including birth and family history and findings on prenatal imaging, if performed. The focused physical examination should include vital signs, general appearance, and abdominal and genital examination. In girls, special attention should be paid to the presence of labial adhesions or intravaginal foreign bodies (Piippo et al., 2000). In boys, special attention should be paid to the presence of phimosis or meatal stenosis, and testicular examination for signs of epididymo-orchitis should be conducted (Merlini et al., 1998).

In febrile newborns with a UTI, 20%–30% have associated bacteremia (Littlewood, 1972; Bachur and Caputo, 1995; Ismaili et al., 2011). As such, a comprehensive work-up for sepsis should be performed in a febrile neonate if there is suspicion of a UTI.

Urine Sample

The easiest method of obtaining a specimen from neonates is with a bag applied to the perineum. However, this carries a high contamination rate with a false-positive urine culture rate of 75%, and its only validity is to rule out a UTI in the event of a negative culture (Leong and Tan, 1976). As always, the culture result must be correlated to a urinalysis, looking for signs of inflammation.

• **Fig. 92.2** International Reflux Study Grading With Voiding Cystourethrogram Examples. (A) In grade I, urine refluxes only into the ureter without reaching the renal pelvis or calyces (notice that it only appears upon voiding in this voiding cystourethrogram example); (B) In grade II, urine refluxes into the ureter, renal pelvis, and calyces, without any dilatation of the collecting system (notice the sharp contours of the fornices); (C) In grade III, urine refluxes into a mildly dilated and tortuous ureter, the renal pelvis, and calyces, with mild blunting of the fornices (notice how the forniceal contours are less sharp); (D) In grade IV, urine refluxes into a moderately dilated and tortuous ureter, the renal pelvis, and calyces, with complete obliteration of forniceal angles but maintenance of papillary impressions; (E) In grade V, urine refluxes into a grossly dilated and tortuous ureter, the renal pelvis, and calyces, with blown fornices where papillary impressions are no longer visible.

A superior method in neonates is urethral catheterization. This yields a sensitivity of 95% and a specificity of 99% for urine culture (Pryles et al., 1959; Pollack et al., 1994). An even more accurate, although more invasive, method is suprapubic aspiration, with a contamination rate of 1% (Tosif et al., 2012). This may be a more appropriate option for boys with tight phimosis and girls with labial adhesions (Tobiansky and Evans, 1998). Topical anesthetics such as Eutectic Mixture of Local Anesthetic may be used to reduce pain associated with suprapubic aspiration in children (Dutta, 1999).

Dipstick urinalysis is an inexpensive and rapid screening tool and tests for urine nitrites and leukocyte esterase. Nitrites in the urine imply the presence of nitrate reductase, which is common among gram-negative uropathogens. Positive detection of leukocyte esterase, which is released by white blood cells (WBCs), is a surrogate for pyuria. In a retrospective study of 13,030 febrile newborns, the sensitivity and specificity of a dipstick urinalysis were 91.7% and 90.4%, respectively. This was comparable with microscopic urinalyses obtained from the same sample population (Glissmeyer et al., 2014).

Microscopic analysis completes the simple dipstick analysis by quantifying the WBCs, red blood cells, and presence of bacteria. Pyuria is the presence of 5 or more WBCs per high power field (HPF) in a centrifuged sample or greater than 10 WBC/HPF in a noncentrifuged sample if a counting chamber is used (Finnell et al., 2011), although these definitions may be less reliable in neonates (Crain and Gershel, 1990).

A urine culture is considered positive when there are 50,000 or more colony-forming units (cfu)/mL of a single bacterial strain on a catheterized or suprapubic specimen or 100,000 or more cfu/mL when a voided sample is cultured (Mori et al., 2010). In combination with a positive dipstick or microscopic urinalysis, a definition of 10,000 or more cfu/mL may be used (Hoberman and Wald, 1997).

Imaging

The optimal approach for imaging in a febrile neonate with a UTI is controversial. Although clear guidelines are set by the AAP for children aged 2 to 24 months, there are no recommendations for neonates (Roberts, 2012). Traditionally, routine imaging with ultrasonography, VCUGs, and renal scans (DMSA) were all recommended for neonates with a febrile UTI (Drew and Acton, 1976). However, recently there has been a shift toward more selective use for DMSA scans and VCUGs because of their ionizing radiation, invasiveness, and cost.

A renal bladder ultrasound in the acute phase is the first-line imaging tool for the investigation of a neonate with a UTI. It is safe, noninvasive, inexpensive, and readily available and should be routinely performed to rule out obstruction, perinephric abscess, and other congenital abnormalities. However, in male neonates with febrile UTIs, Goldman et al. (2000) found VUR in 30% of those with normal ultrasounds. The sensitivity and specificity of predicting all VUR based on an abnormal renal bladder ultrasound are 67% and 77%, respectively (Ismaili et al., 2011). In the same study the sensitivity and specificity increased to 100% and 78%, respectively, when predicting for dilating VUR.

The arguments for routine VCUG in neonates with a febrile UTI revolve around the higher incidence of VUR in this population, which requires aggressive and timely management (Goldman et al., 2000; Cleper et al., 2004). The discussion against the routine use of VCUG is based on evidence that renal scarring is more common with grades IV and V VUR (Ismaili et al., 2011), while the majority

of VUR detected on routine VCUG is grade I–III (Siomou et al., 2009).

It is the author's opinion that the decision to perform a VCUG should be selective, with a thorough discussion with the parents regarding the risks, benefits, and alternatives to the imaging modality. A VCUG should be performed in high-risk neonates such as those with UTIs caused by bacteria other than *E. coli*, those with renal bladder ultrasound abnormalities, and uncircumcised males. If a decision is made to perform a VCUG, it should be performed 2 to 4 weeks after the infection to ensure that the infection is appropriately treated before instrumentation (Cleper et al., 2004).

The debate surrounding the routine use of a DMSA scan is two-fold—first, whether it predicts VUR and second, if it should be performed at all in neonates. Siomou et al. (2009) prospectively followed 72 neonates after their first febrile UTI and found that an early DMSA scan (within the first 72 hours) had poor sensitivity and specificity of 29% and 82%, respectively, for predicting VUR grades III and higher (Siomou et al., 2009). However, the same study showed that an early DMSA scan had a sensitivity and specificity of 100% and 87%, respectively, for predicting permanent renal scarring.

The decision for a DMSA scan should be shared with the parents, taking into account the risk for renal scarring based on the ultrasound findings and grade of VUR (i.e., abnormal renal parenchyma or VUR grade \geq III). The findings of a DMSA scan may contribute to the management plan, providing evidence for or against more aggressive treatment.

Treatment of Urinary Tract Infection

For a febrile neonate a septic work-up should be performed, including a lumbar puncture, complete blood count, urinalysis, urine culture, and blood culture. UTIs in the newborn are considered complicated and are associated with higher incidences of bacteremia (16%–31%) (Ginsburg and McCracken, 1982; Lin et al., 2000). As such, empiric therapy with broad-spectrum antibiotics should be initiated without delay, after blood, urine, and cerebrospinal fluid (CSF) cultures are obtained, to prevent sequelae such as urosepsis and renal scarring.

Candiduria in the neonate indicates systemic disease, and its presence will require consultation with a pediatric infectious disease specialist for further work-up and management.

Local antibiotic resistance patterns and maternal antibiotics history should be used to determine choice of antimicrobial medication for empiric therapy (Allen et al., 1999; Glasgow et al., 2005). The antibiotic should then be changed to one with less broad activity, according to the bacterium's antibiotic sensitivities (Shaikh et al., 2007).

Parenteral ampicillin (50 mg/kg every 8 hours) and gentamicin (2 mg/kg every 12 hours) form the recommended empiric regime for neonates weighing 2 kg or more. In preterm neonates the dose of ampicillin is 150 mg/kg every 12 hours (Pickering et al., 2012). An alternative regime described by the European Association of Urology includes ampicillin with ceftazidime (30–50 mg/kg every 8–12 hours for neonates \geq 2 kg) (Stein et al., 2015).

In young neonates, parenteral therapy should be continued for 7–14 days followed by oral therapy for a total of 14–21 days (Stein et al., 2015). For older and more mature neonates with negative blood and CSF cultures, parenteral antibiotics should be continued for 3–4 days followed by oral therapy for a total of 7–14 days (Pickering et al., 2012).

TABLE 92.1 Randomized Controlled Trials Evaluating the Effect of Continuous Antibiotic Prophylaxis on Urinary Tract Infection Recurrence Rates and Renal Scar Formation

| Authors | Publication Date | PATIENTS INCLUDED | | Randomization | Rate of UTI Recurrence | Renal Scar Formation |

= signifies that these treatments were shown to be equivalent; > signifies that the first listed treatment yields more of the outcome than the second one; < signifies that the first listed treatment yields less of the outcome than the second one.

ARR, Absolute risk reduction; CAP, continuous antibiotic prophylaxis; NNT, number needed to treat; RIVUR, randomized intervention for children with vesicoureteral reflux; UTI, urinary tract infection; VUR, vesicoureteral reflux.

Antibiotic Resistance

In the United States the incidence of ampicillin- and gentamicin-resistant *E. coli* in the neonatal population reaches upwards of 75% and 17%, respectively (Hasvold et al., 2013; Shakir et al., 2014).

Treatment of Vesicoureteral Reflux

Surgical intervention is rarely required in the neonatal period, excluding obstructive abnormalities. If surgery is required, it is reserved for infants with high-grade VUR associated with recurrent breakthrough UTIs and renal scarring. A comprehensive discussion regarding the surgical management of VUR after the neonatal period is beyond the scope of this chapter.

Overall, the management of VUR diagnosed in the neonate after a UTI after the initial evaluation includes close follow-up with renal bladder ultrasounds and selective use of continuous antibiotic prophylaxis (CAP).

Continuous Antibiotic Prophylaxis

The basis for CAP stems from studies in the 1970s showing that the use of long-term antibiotics reduces the risk of repeat positive urine cultures, in comparison with no prophylaxis (Savage et al., 1975; Smellie et al., 1978). In the last 10 years a number of randomized controlled trials (RCTs) have been conducted to elucidate the

role of CAP in preventing UTI recurrences and renal scars. However, evidence for the efficacy of CAP in the neonatal population is lacking. The following discussion is based on study populations older than 1 month of age.

Table 92.1 summarizes these RCTs and their findings. Most fail to show a significant difference in UTI recurrence rate and renal scar formation between those treated with CAP, surveillance, or ureteral reimplantation (Garin et al., 2006; Jodal et al., 2006; Montini et al., 2008; Pennesi et al., 2008; Roussey-Kesler et al., 2008). A Cochrane metaanalysis in 2011 also showed no significant difference in the rate of UTI recurrence between those receiving or not receiving CAP (Nagler et al., 2011). This was further supported by a metaanalysis performed by the AAP using data from six randomized RCTs conducted between 2006 and 2010 encompassing 1091 children with VUR. A two-tailed χ^2 test comparing CAP versus no prophylaxis (surveillance or no treatment) for VUR grades I, II, III, and IV showed no statistically significant benefit from CAP ($P = 1.00, .95, .29$, and $.14$, respectively) (Roberts, 2012).

In 2014 the findings of the Randomized Intervention for Children with Vesicoureteral Reflux (RIVUR) trial were published. RIVUR is the largest randomized, placebo-controlled, double-blind, multicenter study to date investigating the efficacy of CAP compared with placebo in young children with VUR (Carpenter et al., 2013; RIVUR Trial Investigators et al., 2014). This trial, sponsored by

TABLE 92.2 Risk of Breakthrough Urinary Tract Infection Stratification Groups

| Risk Category | Defining Risk Factors | % Found in Population | % Two-Year Risk of Breakthrough UTI | Treatment Suggested |
|-------------------|---|-----------------------|-------------------------------------|-----------------------------------|
| Low risk | <ul style="list-style-type: none"> VUR grade I–III in female without BBD Circumcised male | 67.0 | 8.6 | Surveillance |

BBD, Bladder bowel dysfunction; CAP, continuous antibiotic prophylaxis; UTI, urinary tract infection; VUR, vesicoureteral reflux.

Data from Hidas G, Billimek J, Nam A, et al. Predicting the risk of breakthrough urinary tract infections: primary vesicoureteral reflux. *J Urol*. 2015;194:1396–1401.

the National Institute of Diabetes and Digestive and Kidney Diseases, showed a significantly lower rate of UTI recurrence in children receiving CAP compared with placebo (12.8% vs 25.4%, $P < 0.001$). Furthermore, CAP reduced the risk of UTI recurrence by 50% (hazard ratio 0.50, 95% confidence interval 0.34–0.74) (RIVUR Trial Investigators et al., 2014).

Nevertheless, the results and implications of the RIVUR trial have been widely debated. Critique of the trial includes the homogeneity of the study population. Females and those with VUR grades I–III comprised 91.9% and 91.7% of the study population, respectively (Mattoo et al., 2015). The AAP practice guidelines were recently reaffirmed by the AAP, which suggests that the results of the RIVUR trial may not be clinically significant (Subcommittee on Urinary Tract Infection et al., 2011). The authors acknowledged that a benefit from CAP was demonstrated; however, the number needed to treat (NNT) of 8 translates to a total of 5840 doses of antibiotic to prevent one UTI recurrence.

A lack of evidence for a role for CAP in the neonatal population, coupled with the contentious nature of the current debate over the efficacy of CAP in older children, means that the authors do not have specific recommendations regarding the initiation of CAP in neonates with low-grade VUR.

The decision to start CAP should be made on an individual and selective basis, based on risk for UTI recurrence, in consultation with parents. The use of a clinical calculator (iReflux) developed by Hidas et al. (2015) for determining a child's individualized risk for UTI recurrence may help in this decision. However, it is the author's opinion that in children with high-grade VUR (grades III–V), especially in uncircumcised males, CAP should be initiated (amoxicillin or cephalexin 25 mg/kg daily) (Table 92.2).

Conclusion

In summary, UTIs in neonates can be a serious cause of morbidity, and prompt diagnosis and treatment should be initiated. The presentation, route of infection, work-up, treatment, and spectrum of infecting bacteria are different in neonates compared with older infants and children. The days of a singular approach to treating neonates and older children with UTI and VUR have long disappeared. A new, tailored approach that closely evaluates the known and multiple risk factors that increase a child's risk of recurrence and weighs the effects of concomitant anatomic variations, is necessary to treat each child uniquely and optimally.

Neonatal Hypertension

JOSEPH T. FLYNN

KEY POINTS

- There are numerous influences on normal blood pressure in neonates, including gestational age, birthweight, and maternal factors such as preeclampsia. This makes it difficult to define normal and abnormal blood pressure (BP).
- As in older children, identification of hypertension (HTN) in the neonate is dependent on correct BP measurement technique.
- While the differential diagnosis of systemic HTN in the neonate is broad, common causes include catheter-related thromboembolic phenomena, chronic lung disease, kidney disease, and iatrogenic causes. A focused diagnostic evaluation should lead to correct identification of the underlying cause in most neonates.
- Therapy for HTN in the neonate is largely empiric because of a lack of data on outcomes of elevated BP in neonates and exclusion of neonates from antihypertensive drug trials.

As in other areas of neonatology, advances in the ability to identify, evaluate, and care for premature infants have led to an increased awareness of systemic hypertension in neonates, especially in the neonatal intensive care unit (NICU). However, there is also uncertainty regarding normative blood pressure (BP) in neonates and the best therapeutic approach, mostly because of a lack of rigorous evidence. This chapter will review the many factors that influence BP in the neonate, present what we know about normal neonatal BP, and then move on to a discussion of differential diagnosis of hypertension (HTN), the optimal diagnostic evaluation, and antihypertensive therapy.

Factors That Influence Neonatal Blood Pressure

Many studies have examined the factors that influence BP patterns in normal and premature infants (Versmold et al., 1981; Tan, 1988; Hegyi et al., 1994). Zubrow et al. (1995) examined BPs obtained in more than 600 infants of various birthweights (BW) and gestational ages (GA)s admitted to 14 Philadelphia-area NICUs. They found that BP at birth is closely correlated with GA (Fig. 93.1) and BW (Fig. 93.2). After delivery there is a predictable increase in BP in the first 5 days of life that is independent of these factors. Thereafter, BP continues to rise gradually, with the most important determining factor in the study of Zubrow et al. being postmenstrual (postconceptual) age (Fig. 93.3). A more recent

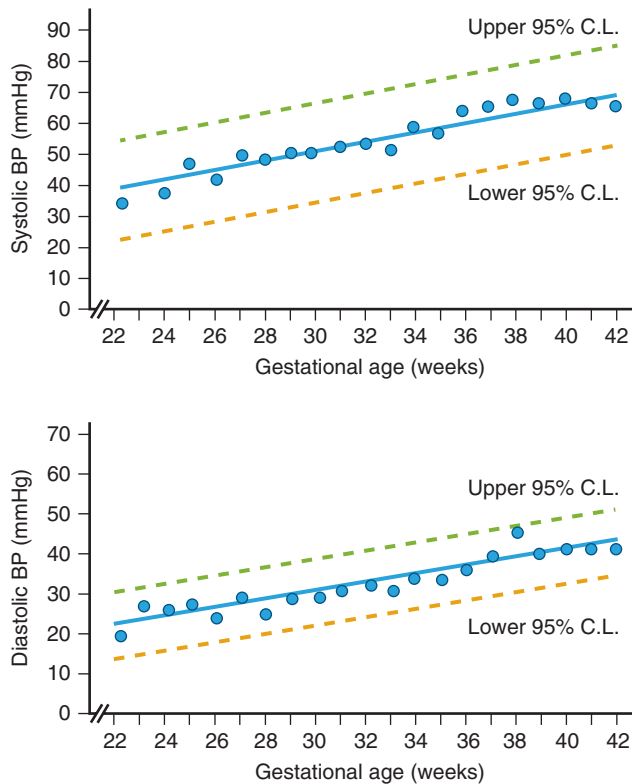

study of stable NICU infants showed a similar pattern, with BPs in each GA category of premature infants increasing at a faster rate during the first week of life, with subsequent slowing (Pejovic et al., 2007); the rate of rise was more rapid in preterm infants than in term infants. Dionne et al. (2012) have summarized available BP data on preterm neonates and have published a table of BPs that is helpful in categorizing an infant's BP as normal or elevated (Table 93.1).

Also important are maternal factors that may influence a neonate's BP. There has been much controversy in the literature regarding the effect of prenatal steroid therapy on infant BP. A randomized controlled trial of corticosteroids versus placebo (Mildenhall et al., 2009) showed no difference in infant BPs between groups. There is some suggestion in the literature that chorioamnionitis and HELLP (hemolysis, elevated liver enzyme levels, low platelet count) syndrome may be associated with lower infant BPs. Higher BPs have been correlated with maternal body mass index greater than 30 kg/m² and low socioeconomic status in a study of Nigerian infants (Sadoh et al., 2010) and in an Australian study of premature infants born to mothers with diabetes or neonates with abnormal uteroplacental perfusion as evidenced by placental pathology (Kent et al., 2009). While these factors may not have caused hypotension or HTN per se, it is clear that many prenatal and postnatal processes combine to influence BP in the newborn period.

Definition of Hypertension

While the definition of HTN in an older infant or child is clear (National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents, 2004), it is more difficult to define HTN in newborns and preterm infants given the changes in BP that normally occur in the first few weeks of life as discussed earlier. After 1 month of age, HTN is defined as systolic and/or diastolic BP equal to or greater than the 95th percentile for that infant's age and sex. Normative values for infants aged 12 months or younger can be found in the curves published in the 1987 Second Task Force report (National Heart Lung and Blood Institute Task Force on Blood Pressure Control in Children, 1987) (Fig. 93.4).

Whether a similar definition can be used for premature neonates is less clear. Dionne et al. (2012) have compiled available data on neonatal BP, and their summary table of BPs (Table 93.1) includes values for the 95th and 99th percentiles for infants of up to 44 weeks' postmenstrual age. They propose that similar criteria for defining HTN in premature neonates as those used in older children can be followed, using the values in Table 93.1 as a guide. It may

• **Fig. 93.1** Correlation between gestational age and neonatal blood pressure (BP). C.L., Confidence limit. (From Zubrow AB, Hulman S, Kushner H, Falkner B. Determinants of blood pressure in infants admitted to neonatal intensive care units: a prospective multicenter study. *J Perinatol.* 1995;15:470–479.)

not be possible to be certain whether this approach is a valid one given the complete lack of any outcome data for hypertensive neonates.

As with older children, the diagnosis of HTN should not be made on the basis of a single reading. If the infant is critically ill and continuous BP monitoring reveals sustained BP elevation over several hours, then HTN should be diagnosed, and appropriate investigation and intervention should be initiated. For less critically ill infants still in the NICU, a pattern of elevated readings over 1 to 2 days should be sufficient to make the diagnosis of HTN. For older infants/NICU graduates who are being followed up as outpatients, at least three elevated readings should be documented over 1 to 2 weeks before a diagnosis of HTN is made (National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents, 2004).

Incidence of Hypertension

Although one recent series found that 28% of very low birth weight (VLBW) infants had at least one elevated BP reading documented during their NICU stay, the actual incidence of HTN in neonates is very low, ranging from 0.2% in healthy newborns to between 0.7% and 2.5% in high-risk newborns (Dionne et al., 2012). The most recently published study demonstrated a 1.3% prevalence of HTN requiring treatment among infants admitted to a teaching hospital NICU (Sahu et al., 2013).

Certain categories of infants are at significantly higher risk, however. For example, HTN is relatively common in patients with a history of umbilical artery (UA) catheterization (3%) and those

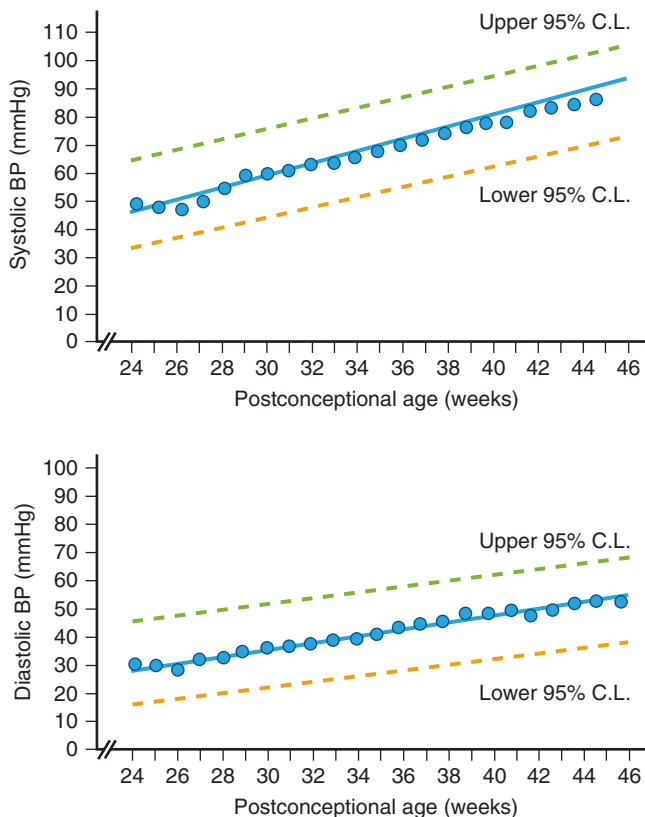

• **Fig. 93.2** Correlation between birthweight and neonatal blood pressure (BP). C.L., Confidence limit. (From Zubrow AB, Hulman S, Kushner H, Falkner B. Determinants of blood pressure in infants admitted to neonatal intensive care units: a prospective multicenter study. *J Perinatol.* 1995; 15:470–479.)

with bronchopulmonary dysplasia (BPD) (as high as 43%). In one series it was also associated with patent ductus arteriosus and intraventricular hemorrhage. On the other hand, HTN is so uncommon in otherwise healthy term infants that routine BP determination is not even recommended (American Academy of Pediatrics Committee on Fetus and Newborn, 1993).

Fewer data are available on the incidence of sustained HTN in NICU graduates. In their classic study, Sheftel et al. (1983) performed BP measurement in infants followed up in a neonatal follow-up clinic and found that 8.9% were hypertensive according to criteria used at that time. A later report by some of the same authors demonstrated an incidence of 2.6% (Friedman and Hustead, 1987). Secondary causes such as those discussed later were found in most cases. Recently, an incidence of elevated BP of 2.9% was seen in a cohort of infants from the neonatology follow-up clinic at the University of Iowa Children's Hospital (Dagle et al., 2011); elevated BP was associated with the cytochrome P450 genotype (*CYP2D6*) in that cohort. Given these data, it is recommended that BP screening be incorporated into the long-term follow-up of NICU graduates.

Etiology and Pathophysiology

While the differential diagnosis of HTN in the neonate or older infant is extensive (Box 93.1), the most important categories of causes of neonatal HTN include renovascular HTN, congenital and acquired renal disease, and BPD.

• **Fig. 93.3** Correlation between postmenstrual (postconceptual) age and neonatal blood pressure (BP). C.L., Confidence limit. (From Zubrow AB, Hulman S, Kushner H, Falkner B. Determinants of blood pressure in infants admitted to neonatal intensive care units: a prospective multicenter study. *J Perinatol.* 1995;15:470–479.)

Renovascular Causes

The most common cause of neonatal renovascular HTN is aortic or renal thromboembolism related to UA catheterization (Bauer et al., 1975). HTN may develop either while the catheter is in place or long after its removal and may be associated with a history of renal insufficiency or gross hematuria. Associated signs may include acute kidney injury (AKI) in patients with bilateral involvement, hematuria, and loss of femoral pulses and blood flow to the lower extremities in patients with extensive aortic thrombosis.

Studies using ultrasound report an incidence of UA-related thromboembolism ranging from 14% to 35%, whereas studies using angiography document incidences up to 64%. Autopsy studies have shown an incidence of UA-related thromboembolism between 9% and 28%, although major clinical symptoms of UA-related thromboembolism occur in 1%–3% of infants (Andrew et al., 2001). Trauma at the time of insertion of an UA catheter caused by endothelial injury is postulated to be the cause of aortic thrombus formation, with clot embolization to the kidneys, causing localized areas of infarction and increased renin release.

Although several studies that have examined the duration of line placement and line position (“low” vs “high”) as factors involved in thrombus formation, the data have not been conclusive. The Cochrane Neonatal Group has attempted to resolve this controversy (Barrington, 2000). It analyzed 11 randomized clinical trials and one study using alternate assignments to compare the incidence of morbidity and mortality for high versus low catheter tip placement. The placement of a catheter tip was defined as high when

it was located in the descending aorta above the diaphragm and low when it was placed in the descending aorta above the bifurcation but below the renal arteries. The reviewers concluded that high catheter position causes fewer clinically obvious ischemic complications. With regard to HTN, however, it was concluded that it seems to appear with equal frequency among infants with high or low catheter placement (Barrington, 2000).

Congenital vascular anomalies responsible for neonatal renovascular HTN include stenosis or hypoplasia of the renal artery and segmental intimal hyperplasia. These conditions may involve the aorta and the renal arteries. Unilateral renal artery stenosis may cause a reversible syndrome characterized by hypokalemic alkalosis, hyponatremia, and increased echogenicity of the contralateral kidney (Castello Girona et al., 1996).

HTN may rarely result from two types of infiltration of the arterial wall. Idiopathic arterial calcification of infancy is characterized by calcium deposits in all layers of the arteries, including the aorta and the coronary arteries, and in the heart valves (Chong and Hutchins, 2008). Some of these deposits may be visible on a plain radiograph. Most cases have been diagnosed at autopsy. HTN typically fails to respond to standard antihypertensive medication

TABLE 93.1**Blood Pressure (mmHg) Percentiles for Neonates up to 44 Weeks' Postconceptual Age**

| Postconceptual Age | 50th Percentile | 95th Percentile | 99th Percentile | Postconceptual Age | 50th Percentile | 95th Percentile | 99th Percentile |

or even to nephrectomy; biphosphonate, calcium antagonists, or prostaglandin infusion may be successful (Ciana et al., 1997), although reported mortality rates are high. Peritoneal dialysis has also been used for management of HTN in at least one recent report (Stojanovic et al., 2013). Galactosialidosis may result in intimal infiltration by sialyloligosaccharides and lead to hyperreninemic HTN (Nordborg et al., 1997).

Other causes of renovascular HTN include neonatal renal arterial embolism in the absence of UA catheterization, intramural hematoma of the renal artery, renal venous thrombosis, and external compression of the renal artery by a hydronephrotic kidney, adrenal hemorrhage, and urinoma. Finally, a neonate with HTN as a result of an aneurysm of the abdominal aorta has been reported (Kim et al., 2001); this fortunately rare condition may present with intractable congestive heart failure.

Bronchopulmonary Dysplasia

Many infants with BPD develop HTN. This phenomenon was first described in the mid-1980s by Abman et al. (1984). In a study of 65 infants discharged from a NICU, the instance of HTN in infants with BPD was 43%, versus 4.5% in infants without

BPD. The investigators were unable to identify a clear cause of HTN but postulated that hypoxemia might be involved. More than half of the infants with BPD who developed HTN did not display it until after discharge from the NICU, further highlighting the need for measurement of BP in NICU "graduates," whether or not they have lung disease.

The findings of Abman et al. have been reproduced by other investigators, including Alagappan and Malloy (1998), who found that HTN was twice as common in VLBW infants with BPD compared with all VLBW infants. Because all of the hypertensive infants required supplemental oxygen and aminophylline, development of HTN appeared to be correlated with the severity of pulmonary disease. Anderson et al. (1993) have demonstrated that the more severe the BPD (defined as a greater need for diuretics and bronchodilators), the higher the likelihood of the development of increased BP. BPD was also noted as a common diagnosis in a recently published case series (Sahu et al., 2013), and infants from the Iowa cohort mentioned previously (Dagle et al., 2011) were more likely to have elevated BP if they required ongoing oxygen therapy after NICU discharge.

These observations reinforce the impression that infants with severe BPD are clearly at increased risk and need close monitoring

• **Fig. 93.4** Normative curves for blood pressure (BP) in infants aged 1 to 2 months. (Data from National Heart, Lung, and Blood Institute Task Force on Blood Pressure Control in Children. Report of the Second Task Force on blood pressure control in children—1987. *Pediatrics*. 1987;79:1–25.)

for the development of HTN. This is especially true in infants who require ongoing treatment with theophylline preparations and/or corticosteroids; as many as 30% of infants receiving dexamethasone for BPD manifest HTN (Ferrara et al., 1990).

Congenital and Acquired Renal Disease

HTN is a common complication of congenital renal anomalies and diseases such as Ask-Upmark kidney, renal hypodysplasia, and obstructive lesions causing hydronephrosis. It is well known that both autosomal dominant polycystic kidney disease and autosomal recessive polycystic kidney disease (ARPKD) may present in the newborn period with severe nephromegaly and HTN (Zerres et al., 1996; Guay-Woodford et al., 2003; Verghese and Miyashita, 2014). With ARPKD the median age of onset of HTN has been reported to be 16 days; most affected infants will be discovered to be hypertensive during the first year of life (Zerres et al., 1996). The most severely affected infants with ARPKD are at risk of development of congestive heart failure as a result of severe, malignant HTN. Bilateral nephrectomy may be lifesaving in such infants.

Although much less common than in polycystic kidney disease, HTN has also been reported in infants with multicystic dysplastic kidneys (Susskind et al., 1989). This is somewhat paradoxical,

as such kidneys are usually thought to be nonfunctioning. The case has been made that HTN in such patients is the result of another coexisting abnormality such as parenchymal scarring (Husmann, 1998). Another possible explanation is increased renin production by macrophages within the dysplastic kidney (Liapis et al., 2002).

Renal obstruction may be accompanied by HTN, even when there is no compression of the renal artery. This has been seen, for example, in infants with congenital ureteropelvic junction obstruction and sometimes may persist following surgical correction of the obstruction. HTN has also been described in infants with congenital primary megaureter. Ureteral obstruction by other intra-abdominal masses may also be accompanied by HTN. The mechanism of HTN in such instances is unclear, although activation of the renin–angiotensin–aldosterone system (RAAS) may be involved (Cadnapaphornchai et al., 1978).

HTN as a result of acquired renal disease occurs less commonly in the NICU than that as a result of congenital renal abnormalities. However, AKI from nephrotoxic or hypoxic acute tubular necrosis, interstitial nephritis, or cortical necrosis may be accompanied by significant HTN, usually as a result of fluid and sodium overload or activation of RAAS. Atypical hemolytic–uremic syndrome, which has been described in both term and preterm infants (Wilson and

TABLE 93.2 Major Features of Monogenic Forms of Hypertension

| | Inheritance Pattern | Age | Potassium Level | Renin Level | Aldosterone Level | Genetic Defect | Therapy |
|---|---------------------|---------|---------------------|-------------|---------------------|--|---|
| Apparent mineralocorticoid excess | AR | I, C, A | Decreased or normal | Decreased | Decreased | Loss of function in 11- β -HSD2 gene | Spironolactone, eplerenone |
| Glucocorticoid remediable aldosteronism | AD | I, C | Decreased or normal | Decreased | Decreased or normal | Chimeric gene; fusion of aldosterone synthase and 11- β -hydroxylase genes | Amiloride, triamterene, glucocorticoids |
| Congenital adrenal hyperplasia | AR | I | Decreased or normal | Decreased | Decreased | Loss of function in 11- β -hydroxylase or 17 α -hydroxylase gene | Spironolactone, eplerenone |
| Liddle syndrome | AD | C, A | Decreased or normal | Decreased | Decreased | Gain of function in ENaC gene | Amiloride, triamterene |
| Gordon syndrome | AD | A, C | Increased or normal | Decreased | Increased or normal | Gain of function in WNK1 gene; loss of function in WNK4 gene | Thiazide |

A, Adulthood; AD, autosomal dominant; AR, autosomal recessive; C, childhood; ENaC, epithelial sodium channel; 11- β -HSD2, 11- β -hydroxysteroid dehydrogenase2; I, infancy; WNK, WNK lysine-deficient protein kinase.

Flynn, 1998), is usually also accompanied by HTN. Such HTN may be extremely difficult to control, requiring treatment with multiple agents.

Genetic Causes

Genetic forms of HTN that may present in the neonatal period fall into two broad categories: namely, HTN resulting from a single-gene disorder and HTN occurring as one feature of a malformation syndrome. Single-gene disorders causing HTN with reported cases in infancy include Liddle syndrome, glucocorticoid-remediable aldosteronism, and Gordon syndrome (pseudohypoaldosteronism type II). A summary of the major features of these disorders is presented in Table 93.2; for a detailed discussion of monogenic HTN, the reader should consult other references (Simonetti et al., 2012; Toka et al., 2013).

Malformation syndromes that may cause HTN include Williams syndrome (renal artery stenosis), Turner syndrome (aortic coarctation), neurofibromatosis (renal artery stenosis, coarctation), and Cockayne syndrome. Usually the HTN in these syndromes presents beyond the neonatal period, but infantile presentations with HTN have been described.

Miscellaneous Causes

Coarctation of the thoracic aorta (see Chapter 55) has been reported in numerous case series of neonatal HTN. Although usually detected in the newborn period on the basis of decreased pulses and lower BPs in the lower extremities compared with the upper extremities, the similarity of upper and lower extremity BP readings in early infancy means that echocardiography is needed for definitive diagnosis (Crossland et al., 2004). HTN may persist or recur in these patients even after surgical repair of the coarctation (O'Sullivan et al., 2002). Repair early in infancy seems to lead to an improved long-term outcome compared with delayed repair.

Endocrine disorders, particularly congenital adrenal hyperplasia, hyperaldosteronism, and hyperthyroidism, constitute easily recognizable clinical entities that have been reported to cause HTN in

neonates (White, 1996). Several adrenal disturbances can induce HTN directly; they should be differentiated from Liddle syndrome. Hyperthyroidism is associated with systolic HTN and sustained tachycardia and, sometimes, with episodes of supraventricular tachycardia (Schonwetter et al., 1983).

Tumors, including neuroblastoma, Wilms tumor, and mesoblastic nephroma, may present in the neonatal period and may produce HTN, either because of compression of the renal vessels or ureters or because of production of vasoactive substances such as renin or catecholamines.

Neurologic causes of HTN include intracranial HTN, drug withdrawal, seizures, pain, and familial dysautonomia. Seizures are common complications of severe HTN; in turn, BP may increase transiently during seizure episodes (Perlman and Volpe, 1983). Appropriate pain relief should be given before and after surgical procedures.

Iatrogenic causes of neonatal HTN are common and usually obvious but are important to consider. If the infant is hypervolemic secondary to excessive administration of sodium or fluids, intake should be restricted, and a diuretic should be administered. It is imperative to eliminate hidden sources of sodium, such as isotonic saline used to flush an arterial line and sodium-containing medications (e.g., antibiotics). If HTN is induced by a medication, one may consider withholding it, decreasing the dose, or using an infusion instead of repeated injections. As noted earlier, dexamethasone may cause BP elevation relatively commonly (Ferrara et al., 1990; Smets and Vanhaesebrouck, 1996); if this occurs, a decision must be made regarding the possible benefits of continued steroid treatment versus the risks of HTN. HTN induced by pancuronium is probably related to catecholamine release; BP may normalize after substitution of vecuronium for pancuronium.

HTN develops in 11%–92% of neonates receiving extracorporeal membrane oxygenation (Boedy et al., 1990; Blowey et al., 2011) and may result in serious complications, including intracranial hemorrhage and increased mortality. Despite extensive investigation, the exact pathogenesis of this form of HTN remains poorly understood. Fluid overload, altered renal sodium and water handling,

and altered baroreceptor function have all been proposed as causative factors. Nicardipine infusions are commonly used to treat this form of HTN.

HTN may develop after surgery. Of four patients who developed HTN after surgical repair of an abdominal wall defect, three had edema of the lower extremities and normal plasma renin activity (PRA), and one had evidence of ureteropelvic junction obstruction and high PRA (Adelman and Sherman, 1980). The duration of HTN in these patients ranged from 12 days to 6 months. A more recent case series demonstrated that HTN is more frequent and more persistent in patients with omphalocele than in patients with gastroschisis (Cachat et al., 2006). HTN appearing after primary closure for bladder exstrophy may be related to traction for skeletal immobilization (Husmann et al., 1993).

Diagnostic Evaluation

The first step in the evaluation is to make sure the BP is being measured correctly; this is discussed in detail in the next section. After that it is important to determine whether the infant is persistently hypertensive or if the BP rises only during periods of agitation, pain, crying, feeding, or performance of procedures. Only in infants with correctly measured BP and persistent BP elevation should the “diagnosis” of HTN be made and diagnostic work-up be initiated.

Blood Pressure Measurement

Some neonates have their BP measured directly through an indwelling UA catheter; this technique provides the most accurate method of measuring BP, except for minor artifacts from air bubbles or blood clots in the tubing (Rothe and Kim, 1980). The most commonly used indirect method of BP measurement is the oscillometric technique, which directly measures mean arterial pressure (MAP) on the basis of the oscillations of the arterial wall as the cuff is deflated; systolic and diastolic BP are then back-calculated from the MAP with use of manufacturer-specific algorithms. Although the readings obtained by oscillometric devices may differ between 1 and 5 mmHg compared with directly measured BP, these devices are usually sufficiently accurate for routine clinical use (Low et al., 1995). Of note, shock may lead to inaccurate oscillometric measurements (Kimble et al., 1981). Despite these issues, oscillometric devices are clearly useful for measuring BP in infants without indwelling arterial catheters (especially those who require frequently repeated BP measurement) and in infants who have been discharged from the nursery.

Selection of a proper sized cuff is crucial for correct indirect BP measurement. The cuff bladder length should encircle 80%–100% of the arm circumference; a cuff bladder with a width-to-length ratio of 0.45–0.55 is recommended (Kimble et al., 1981; Sonesson and Broberger, 1987). A full range of “neonatal” cuff sizes will need to be available for outpatient follow-up of NICU graduates. If BP is measured in the calf, it is important to use a wide enough cuff; cuffs designed for use in the upper arm may be too narrow, resulting in a falsely high BP reading. Calf BPs are generally the same as upper arm BPs in neonates, and this similarity has been shown to persist for as long as the first 6 months of life. This has implications for the diagnosis of coarctation of the aorta in neonates (Park and Lee, 1989; Crapanzano et al., 1996; Crossland et al., 2004).

BP increases when an infant is awake, in the knee–chest position, with crying, pain, and during physical examination and procedures,

• **Fig. 93.5** Effect of infant state on blood pressure (BP). DBP, Diastolic blood pressure; SBP, systolic blood pressure. (From Satoh M, Inoue R, Tada H, et al. Reference values and associated factors for Japanese newborns' blood pressure and pulse rate: the babies' and their parents' longitudinal observation in Suzuki Memorial Hospital on intrauterine period (BOSHI) study. *J Hypertens*. 2016;34:1578–1585.)

or during feeding (Spahr et al., 1981; Sinkin et al., 1985; Park and Lee, 1989). A recent study from Japan of BP in 3148 newborns demonstrated the effects on BP of various states of activity (Fig. 93.5; Satoh et al., 2016). Even pacifier use during sleep has been shown to increase BP (Yiallourou et al., 2014). Because of these factors, it is important to follow a standard approach for BP measurement in neonates; the protocol described by Nwankwo et al. (1997) is appropriate. Measurements in NICU graduates should be obtained only when the infant is asleep or calm (Duncan et al., 2008).

History and Physical Examination

In most neonates suspected of having HTN, a relatively focused history can be obtained, paying attention to determining whether there were any relevant prenatal exposures and to the particulars of the infant's NICU/nursery course and any concurrent medical conditions/complications of prematurity. The procedures that the infant has undergone (e.g., umbilical catheter placement) should be reviewed, and the current medication list should be scrutinized. Easily identifiable causes of HTN such as fluid overload or medication-induced HTN should be able to be identified at this stage, and appropriate countermeasures should be taken to correct the problem.

The physical examination should similarly focus on identifying obvious problems that may be causing the BP elevation. BP readings should be obtained in all four extremities to rule out coarctation of the thoracic aorta. The general appearance of the infant should be assessed, with particular attention paid to the presence of dysmorphic features. Careful cardiac and abdominal examinations should be performed, as specific findings (heart murmur, unilateral flank mass, ambiguous genitalia, etc.) can help direct subsequent diagnostic testing.

Diagnostic Testing

If the infant's HTN appears to be iatrogenic or secondary to drug withdrawal, specific therapy can be instituted without performance

TABLE 93.3 Diagnostic Studies

| Generally Useful | Useful in Selected Infants |
|--|---|
| Urinalysis (with or without culture) | Thyroid studies |
| Complete blood count and platelet count | Aldosterone |
| Electrolytes | Cortisol |
| Blood urea nitrogen, creatinine | Urine vanillylmandelic acid/homovanillic acid |
| Calcium | Plasma catecholamines/metanephrines |
| Plasma renin | Echocardiogram |
| Chest X-ray | Abdominal/pelvic ultrasonography |
| Renal ultrasonography with Doppler measurement | Voiding cystourethrogram |
| | Renal angiography |
| | Nuclear scan (DTPA/MAG-3) |

DTPA, Diethylenetriaminepentaacetic acid; MAG-3, mercaptoacetyltriglycine.

of additional investigation. If no cause is evident, then urinalysis and screening chemistry tests should be performed (Table 93.3). If a renal or renovascular cause is suspected, the work-up will usually include ultrasonography of the kidneys, adrenal glands, aorta, and bladder, with a flow study (i.e., Doppler ultrasonography) of the aorta and the renal arteries and renal veins. Usually a chest X-ray is useful if one has not been obtained recently. An echocardiogram will be needed to confirm the diagnosis of aortic coarctation. Nuclear renal scans, angiography, magnetic resonance imaging, or computed tomography may be indicated in specific patients. If there is any suspicion of hydronephrosis or vesicoureteral reflux, urine obtained by suprapubic aspiration or bladder catheterization should be sent for bacterial and fungal culture.

PRA should be measured as part of the work-up in most hypertensive infants. The PRA is most helpful if it is extremely low—in such cases, a single-gene disorder affecting renal sodium transport should be suspected (see the preceding discussion on genetic causes). Elevated PRA is less helpful as it may be secondary to the administration of diuretics or adrenergic medications or may be secondary to severe respiratory disease; mild elevations of PRA may be seen in normal infants.

Other blood studies listed in Table 93.3 should be reserved for selected infants when there is a suggestion from the history, physical examination, and/or screening studies that a specific secondary cause of HTN may be present. Usually it is best to obtain the assistance of the appropriate subspecialist (nephrologist, endocrinologist, oncologist, etc.) before such studies are ordered.

Treatment

Treatment of neonatal HTN should begin with correction of any iatrogenic causes such as fluid overload or medications that increase BP. After that, a decision needs to be made as to whether antihypertensive medications are indicated. Clearly infants with severe, symptomatic HTN should receive immediate treatment. However, in those with less severe HTN, particularly those in whom the high BP does not appear to be causing any immediate problem, the necessity of initiating treatment with antihypertensive medications is often unclear. We do not know whether HTN in such infants affects long-term outcomes, and we certainly do not know at what BP target-organ effects begin to appear. Furthermore, no clinical trials of antihypertensive medications have ever been

conducted in neonates, so there are no data on efficacy or safety in this population. Thus a great deal of individual judgment must be brought to bear in deciding to treat HTN in the NICU.

That said, we would certainly recommend that critically ill infants with acute onset of severe HTN should be treated with an intravenous agent administered by continuous infusion, as this will allow the greatest control of the rate and magnitude of the BP reduction. These infants should have their BP lowered by no more than 25% in the first 8 hours to prevent cerebral ischemia (Flynn and Tullus, 2009). On the other hand, relatively well infants with mild HTN may be treated with oral antihypertensive agents. Recommended doses for intravenous and oral antihypertensive drugs in neonates can be found in Table 93.4.

The choice of oral antihypertensive medication to use in hypertensive neonates is somewhat controversial. Available data indicate that hypertensive infants are treated with a wide variety of classes of antihypertensive agents (Blowey et al., 2011). Whereas angiotensin-converting enzyme (ACE) inhibitors are considered the drugs of choice for adults and children with renal forms of HTN and although there is a long history of their use in neonatal HTN, many neonatologists and pediatric nephrologists have serious concerns about the potential major side effects, such as excessive hypotension, AKI (Gantenbein et al., 2008), and neurologic abnormalities. There may also be adverse effects on the completion of renal development in premature neonates. Other medications, such as a β -blocker or, in the case of a hypertensive crisis, a potent vasodilator, should be tried first. The advantage of a β -blocker such as propranolol is that it reduces the secretion of renin and the release of norepinephrine; however, it may also cause bronchoconstriction or hypoglycemia, making its use problematic in some infants.

Of the available vasodilators, the calcium channel blockers isradipine and amlodipine have found widespread use in neonates (Dionne et al., 2012). Older vasodilating agents such as hydralazine and minoxidil may also be useful in selected infants or when the newer agents are not available. Clonidine is yet another potential choice. All oral antihypertensive medications excepting propranolol need to be compounded into suspensions by the hospital pharmacy.

Of the many intravenous antihypertensive agents available, nicardipine has emerged as the most useful for management of severe neonatal HTN (Gouyon et al., 1997; Milou et al., 2000). It can be precisely titrated to the desired antihypertensive effect, and its use may be continued for prolonged periods without loss of antihypertensive efficacy. A possible issue is the need to infuse nicardipine through a central line. Alternative agents that may be given by continuous infusion include esmolol, hydralazine, labetalol, and sodium nitroprusside. Esmolol and labetalol may be contraindicated in infants with lung disease, and nitroprusside can be used only for limited periods (usually <72 hours) because of the accumulation of thiocyanate.

Intravenous antihypertensives that can be administered by intermittent bolus injection include hydralazine and labetalol. The intravenous ACE inhibitor enalaprilat has been reported to be effective in cases of severe neonatal HTN in one small case series (Wells et al., 1990); however, our anecdotal experience suggests that this agent may cause sudden, oliguric acute renal failure similar to that reported for orally administered enalapril (Dutta and Narang, 2003). Given this, we do not recommend use of enalaprilat in neonates.

Surgery is indicated for treatment of neonatal HTN in a limited set of circumstances (Rajpoot et al., 1999). In particular, HTN

TABLE 93.4 Recommended Dosing of Selected Antihypertensive Agents in Neonates

| Class | Drug | Route | Dose | Interval | Comments |
|--------------------------|----------------------|-------|--|----------|--|
| ACE inhibitors | Captopril | Oral | <3 months: 0.01–0.5 mg/kg/dose Maximum 2 mg/kg per day >3 months: 0.15–0.3 mg/kg per dose Maximum 6 mg/kg per day | TID | 1. First dose may cause rapid drop in BP, especially if receiving diuretics. 2. Monitor serum creatinine and K ⁺ levels. |
| | Enalapril | Oral | 0.08–0.6 mg/kg per day | BID | |
| | Lisinopril | Oral | 0.07–0.6 mg/kg per day | QD | |
| α and β antagonists | Labetalol | Oral | 0.5–1.0 mg/kg/dose up to 10 mg/kg per day | BID–TID | Heart failure, BPD relative contraindications |
| | | IV | 0.20–1.0 mg/kg per dose (bolus) | Q4h–Q6h | |
| | Carvedilol | IV | 0.25–3.0 mg/kg per hour | Infusion | |
| β antagonists | Esmolol | Oral | 0.1 mg/kg/dose up to 0.5 mg/kg per dose | BID | May be useful in heart failure |
| | | IV | 100–500 µg/kg per min | Infusion | |
| | Propranolol | Oral | 0.5–1.0 mg/kg per dose Maximum 8–10 mg/kg per day | TID | Very short acting—constant infusion necessary Monitor heart rate; avoid in BPD |
| Calcium channel blockers | Amlodipine | Oral | 0.05–0.3 mg/kg per dose up to 0.6 mg/kg per day | QD | All may cause mild reflex tachycardia. |
| | Isradipine | Oral | 0.05–0.15 mg/kg per dose up to 0.8 mg/kg per day | QID | |
| | Nicardipine | IV | 0.5–4 µg/kg per min | Infusion | |
| Central α agonist | Clonidine | Oral | 5–10 µg/kg per day up to 25 µg/kg per day | TID | May cause mild sedation |
| Diuretics | Chlorothiazide | Oral | 5–15 mg/kg per dose | BID | Monitor electrolyte levels. |
| | Hydrochlorothiazide | Oral | 1–3 mg/kg per dose | QD–BID | |
| | Spironolactone | Oral | 0.5–1.5 mg/kg per dose | BID | |
| Vasodilators | Hydralazine | Oral | 0.25–1.0 mg/kg per dose up to 7.5 mg/kg per day | TID–QID | Tachycardia and fluid retention are common side effects. |
| | | IV | 0.15–0.6 mg/kg per dose | Q4h | |
| | Minoxidil | Oral | 0.1–0.2 mg/kg per dose | BID–TID | Tachycardia and fluid retention are common side effects; prolonged use causes hypertrichosis. |
| | Sodium nitroprusside | IV | 0.5–10 µg/kg per min | Infusion | Thiocyanate toxicity can occur with prolonged (>72 h) use or in renal failure. |

Use of any of these medications in neonates should be considered off-label.

ACE, Angiotensin-converting enzyme; BID, twice daily; BP, blood pressure; BPD, bronchopulmonary dysplasia; IV, intravenous; K⁺, potassium; QD, once daily; Q4h, every 4 hours; Q6h every 6 hours; QID, four times daily; TID, three times daily.

caused by urologic causes such as ureteropelvic junction obstruction or aortic coarctation is best approached surgically. On the other hand, most infants with renal artery stenosis will need to be treated medically until they have grown sufficiently to undergo definitive repair of the vascular abnormalities, although case reports of successful intervention in infancy have been published (Peco-Antic et al., 2006). Infants with HTN secondary to Wilms tumor or neuroblastoma will require surgical tumor removal, possibly following chemotherapy. A case has also been made by some authors for prophylactic removal of multicystic dysplastic kidneys because of the risk of development of HTN (Webb et al., 1997), although this is controversial.

Prognosis

The prognosis of neonatal HTN depends on the cause, timing of the diagnosis, presence of complications, and response to therapy. Patients with severe HTN and neurologic, cardiovascular, or renal

decompensation have a high mortality rate. As previously mentioned, the mortality rate of patients with idiopathic calcification of the arteries or with massive aortic thrombosis remains high despite aggressive therapy. Although data are limited, the long-term prognosis for newborns with HTN related to thromboembolism or BPD appears to be good, often with progressive resolution of the HTN within 6 to 12 months of age (Seliem et al., 2007). On the other hand, patients with parenchymal renal disease, especially those with persistent renal dysfunction following NICU discharge, are likely to have persistent HTN throughout childhood. Infants who undergo repair of aortic coarctation are at long-term risk of persistent or recurrent HTN later in childhood and require continued follow-up (O'Sullivan et al., 2002).

Developmental Endocrinology

SARA A. DIVALL AND LINA MERJANEH

KEY POINTS

- Endocrine organ function in neonates is dependent on organ development as well as the maternal, placental, and fetal hormone milieu.
- Fetal adaptation or maladaptation to the hormonal milieu may contribute to neonatal disease.
- Developmental disorders of endocrine organs often manifest themselves in the neonatal period.
- The fetal adrenal gland produces large amounts of androgens to be used by the placenta for estrogen biosynthesis.
- Maternal cortisol is inactivated by placental enzymes that convert cortisol to inactive cortisone.
- Neonatal hypopituitarism may be due to a number of specific gene mutations with or without defects in other cranial structures.
- The fetal adrenal gland increases in size during gestation to 10–20 times the size of adult adrenal glands. Rapid involution and decrease in size occur after birth.
- The thyroid emerges from the pharyngeal floor and then migrates caudally to its final destination in the anterior neck. Abnormalities in thyroid descent result in ectopic thyroid, thyroglossal duct, or cysts.
- Pancreatic β -cell differentiation and proliferation are dependent on insulin-like growth factor 2.
- The placenta actively transports maternal calcium, phosphorus, and magnesium to maintain high fetal serum levels necessary for the developing skeleton.

Like development of other fetal organ systems, development of the endocrine system involves integration of complex genetic, cellular, and hormonal cues as well as the coordinated action of transcription factors, signaling molecules, and epigenetic regulation. Additionally, endocrine communication is necessary for the vital maternal–placental–fetal interaction because endocrine signals are the tools that cells and organs use to communicate with each other. In this chapter, we will first discuss basic concepts of hormonal systems and then discuss the unique hormonal milieu of the placenta that allows maternal–fetal communication and fetal growth. The development of each of the classic endocrine organs will then be discussed. Finally, the developmental origins of the adult disease hypothesis will be discussed.

Endocrine Systems

A few key concepts of cell communication will be presented here to assist in the building of a foundation of knowledge to understand hormonal abnormalities in neonates.

In the process of communication, cells emit signals that act locally or distally. If a cell emits signals that are received by the cell itself, this is termed *autocrine regulation*. If a cell emits signals that are received by neighboring cells, this is termed *paracrine regulation*. Finally, if the cell signal travels through the bloodstream to distant cells and organs, this is termed *endocrine regulation*.

A feature of endocrine systems is the fact that the hormonal signals are present in the bloodstream at very low concentrations, and even small changes in hormone concentration can elicit a robust response from receiving cells. The released endocrine hormone can be either water-soluble peptide hormones that must bind to receptors on the extracellular surface of the cell or fat-soluble steroid-like molecules that can pass through the cell membrane directly into the nucleus of the cell to bind its receptor, to regulate gene transcription. On binding to their specific cell membrane receptor, peptide hormones activate downstream signaling transduction pathways in the cell to induce biological responses. These responses can be immediate; for instance, thyroid-stimulating hormone (TSH), when bound to the TSH receptor on thyroid follicular cells, cause iodine transport into the cell to increase. It can also induce cell responses that are relatively delayed, such as an increase in gene transcription of enzymes involved in thyroglobulin production. In contrast, steroid-like molecules, such as cortisol, when bound to their respective receptors induce a biological response by causing an increase in transcription of various genes. These induce longer term, broader changes in the target cell function by modulating which genes the cells express and thus the proteins they produce.

Many hormonal systems exhibit a hierarchy of hormone signals that allow strict regulation of system function. The hypothalamic–pituitary–end gland system is an example of this multitier hormonal system. In this system, hormone released by the upstream hypothalamus travels through the portal circulation of the pituitary and binds to the corresponding receptor on the dedicated pituitary cell. Once bound, this receptor induces the cell to synthesize and release the corresponding pituitary hormone. This hormone in turn then travels through the systemic circulation to the endocrine gland to bind to the hormone’s dedicated receptor on the target

gland. Binding of the hormone to its receptor induces the target organ to then release its dedicated end hormone. This hormone then travels through the bloodstream to multiple organs to affect cell function. End hormones use negative feedback to regulate their own production. That is, the hypothalamus and pituitary sense the end hormone concentration, adjusting release of the upstream, regulatory hormone cascade to fine-tune end hormone production. Negative feedback is a unique and consistent property of hormonal systems and is useful in interpreting adequate response of a hormonal cascade to perturbation in the system.

Endocrine Organ Development and Perinatal Transition

Early in fetal development, fetal hormonal gland development is driven by fetal genotype. However, later in fetal development, the hormonal responsiveness of target tissues is dependent not only on fetal genotype but also on the complex fetal hormonal milieu, which comprises fetal, maternal, and placental hormones. Placental hormones may be influenced by maternal and fetal genotype, as well as maternal prepregnancy and pregnancy health and nutrition. Thus the fetal hormonal environment is dependent on a complex interplay between fetal and maternal factors.

In evaluating hormonal disorders in newborns, one needs to consider both maternal and fetal factors and keep the following principles in mind. First, human fetal endocrine organ development begins predominantly independently of maternal hormones. This is possible because the placenta is a barrier to many (but not all) maternal hormones, including steroids, peptides, and glycoproteins. Second, although endocrine organ development may be normal, perturbations in the maternal hormonal milieu may still affect fetal development for the rare hormone that crosses the placenta. This finding is found in disorders of thyroid hormone production. Maternal–fetal transfer of thyroxine (T_4) may result in 25%–50% of neonatal plasma levels of T_4 (Vulsma et al., 1989). This transfer allows children with athyrosis to have good neurodevelopmental outcomes if treatment is initiated within 2 weeks of birth, as the maternal thyroid hormone crossed the placenta and allowed normal fetal neurodevelopment and growth. In contrast, children born to mothers with untreated or undertreated hypothyroidism during pregnancy have poor neurodevelopmental outcomes because of the hypothyroxinemia early in gestation before T_4 production by the fetal thyroid (Haddow et al., 1999; Yasuda et al., 1999). Third, alterations in transplacental substrate transfer can modify late development of the fetal and thus neonatal hormonal pathway and feedback mechanisms. This can be seen in neonates born from pregnancies with uncontrolled diabetes, in which the transplacental passage of glucose induces robust insulin release and subsequent β -cell hypertrophy in the still developing pancreas. This leads to transient neonatal hyperinsulinemic hypoglycemia as a consequence of the abrupt fall in glucose supply at birth. This is also seen in the placental transfer of hormonal agents or maternal antibodies that affect neonatal endocrine gland function. Examples include the transplacental crossing of maternal TSH antibodies causing neonatal hyperthyroidism. Fourth, knowledge of endocrine developmental biology has been obtained from large animal fetal physiology models and gene manipulation studies in mice. When comparing ontogenic studies performed in different species, one must consider similarities and differences from human fetuses and newborns. The maturational state at birth differs widely among species. For many species, including rodents

and some large animals, the maturational state of the newborn is relatively immature (altricial). Organ systems in humans, in contrast, are relatively more developed at birth (precocial). This is especially true in neuroendocrine and most endocrine systems. Thus study of hormonal physiology in newborn mice may yield insights, but they may not be immediately applicable to human newborns.

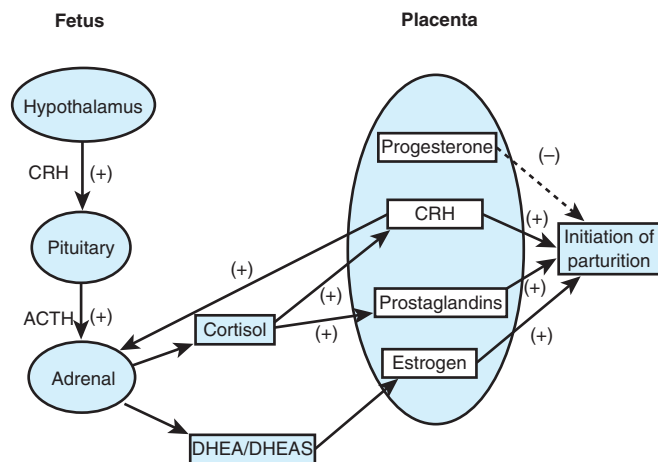

The Maternal–Placental–Fetal Unit

During pregnancy the mother, fetus, and placenta function in concert as a steroidogenic unit for estrogen and progesterone production. Most steroidogenic activity is exerted in the fetal zone (FZ) of the human fetal adrenal (HFA) gland, where large amounts of adrenal androgens are produced to be used by the placenta for estrogen biosynthesis. Estrogen promotes placental trophoblast differentiation into syncytiotrophoblast and upregulates key enzymes in progesterone biosynthesis (Mesiano and Jaffe, 1997).

Cortisol may act as a “two-edged sword” for the fetus; it promotes maturation of fetal organs necessary for extrauterine life, but it can also adversely influence fetal growth and postnatal development. Therefore cortisol production in the fetoplacental unit is strictly regulated to protect the fetus from hypercortisolism effects. Fetal access to maternal glucocorticoid is restricted, and a maternal–fetal gradient is maintained by the enzyme 11β -hydroxysteroid dehydrogenase type 2, which converts cortisol to inactive cortisone. Maternal cortisol levels are usually 5 to 10 times higher than fetal cortisol levels. Fetal protection is also achieved through other mechanisms in the HFA by regulation of 3β -hydroxysteroid dehydrogenase/ Δ^{4-5} isomerase type 2, the key steroidogenic enzyme for cortisol biosynthesis, and in fetal membranes by control of 11β -hydroxysteroid dehydrogenase type 1 activity, which converts inactive cortisone to cortisol (Ishimoto and Jaffe, 2011). A single course of glucocorticoids is universally accepted as a standard therapy for pregnant women at risk of preterm delivery to accelerate fetal lung maturation and reduce morbidity and mortality in preterm infants (Roberts and Dalziel, 2006). However, multiple courses of glucocorticoids prenatally may be associated with decreased weight, length, and head circumference at birth (Murphy et al., 2008).

Placental corticotropin-releasing hormone (CRH) is one of the key determinants of the timing of parturition. Near term, its level increases and directly stimulates the HFA by increasing its responsiveness to adrenocorticotrophic hormone (ACTH) and secretion of cortisol and dehydroepiandrosterone (DHEA) and its sulfonated form, precursors of placental estrogen. Cortisol, in turn, stimulates placental CRH production, forming a positive feedback loop and generating more cortisol and estrogen near term. Estrogen upregulates contraction-associated proteins and transforms the myometrium into a contractile state, preparing for successful uterine contractions and parturition. Cortisol also promotes maturation of fetal organs (e.g., the lung) and stimulates production of prostaglandins necessary for parturition. Increased levels of estrogen, cortisol, and CRH, together with functional progesterone withdrawal, are thought to contribute to the initiation of parturition (Sirianni et al., 2005; Mendelson, 2009; Fig. 94.1).

From this perspective, one would expect that the lack of the increased cortisol production observed near term in preterm infants may have adverse consequences. This is not confirmed; some studies showed no adverse effects related to low cortisol levels in preterm infants (Aucott et al., 2008), while others correlated low cortisol levels to increased severity of illness, hypotension, mortality, and

• **Fig. 94.1** Endocrine Cascades in the Fetoplacental Unit That Lead to Initiation of Parturition. Near term, production of placental corticotropin-releasing hormone (CRH) increases and stimulates fetal adrenal glands to produce dehydroepiandrosterone (DHEA)/dehydroepiandrosterone sulfate (DHEAS) and cortisol. Increased cortisol production stimulates production of placental CRH through a positive feedback loop. DHEA/DHEAS is converted by the placenta to estrogen, promoting initiation of parturition through upregulation of contraction-associated proteins. Cortisol and CRH also stimulate production of prostaglandins necessary for contractions. When “functional withdrawal” of progesterone occurs, coupled with these changes, parturition is initiated. ACTH, Adrenocorticotropic hormone.

development of bronchopulmonary dysplasia (Watterberg et al., 2007). Selective hydrocortisone supplementation for at-risk infants may be used for care of these infants.

Umbilical plasma estradiol and progesterone levels are quite high and fall by approximately 100-fold during the first day after birth. The consequences of estradiol and progesterone withdrawal earlier in premature infants remain largely unknown. Pilot studies of estradiol and progesterone supplementation in extremely low-birthweight infants have shown trends toward increased bone mineralization and a decrease in the incidence of chronic lung disease (Trotter et al., 2001, 2007). More powered clinical trials are needed to determine the benefits and risks of hormonal replacement in preterm infants.

Hypothalamic and Pituitary Development

The anterior and posterior pituitary glands have different embryonic origins. The anterior lobe arises from oral ectoderm, and the posterior pituitary arises from the infundibulum of the developing central nervous system. A section of the oral ectoderm thickens very early in development, forming an invagination termed a *Rathke pouch*. As the Rathke pouch invaginates further, the adjacent neural ectoderm evaginates to form the infundibulum (Fig. 94.2A). With further evagination, the Rathke pouch and the infundibulum directly contact each other. This close contact is important for subsequent anterior and posterior pituitary development. The Rathke pouch later “pinches off” from the remaining oral ectoderm

• **Fig. 94.2** Pituitary Gland Development. (A) Simplified schematic of anterior pituitary development from oral ectoderm via evagination into the Rathke pouch, with subsequent pinching off of tissue to separate from oral ectoderm and eventually form the anterior pituitary. (B) The transcription factor cascade implicated in pituitary development and cell differentiation. to form the anterior pituitary gland. In humans this occurs by 5 to 6 weeks' gestation.

The hypothalamus comprises a diverse collection of neurons that regulate pituitary hormone release, thirst, body temperature, blood pressure, and serum osmolality. Although the location of the diverse neurons within the hypothalamus is well delineated, the development of these diverse neuron populations within the hypothalamus has yet to be elucidated. The complexity of the anatomy and neuronal cell types makes it difficult to elucidate the developmental cascade of events. Nevertheless, it is known that the hypothalamic nuclei, which contain the individual neuron types, are fully developed with projections to the median eminence (with subsequent release of hormone into the pituitary portal circulation) by 15 to 18 weeks' gestation (Kelberman et al., 2009).

In contrast, knowledge regarding differentiation of the anterior pituitary is well delineated. Differentiation of Rathke pouch cell progenitors into the pituitary cell types (corticotrophs, gonadotrophs, lactotrophs, thyrotrophs, and somatotrophs) is tightly regulated by a cascading series of transcription factors (see Fig. 94.2B). Knowledge of the series of events is from knockout studies in mice as well as genetic studies in humans with congenital hypopituitarism. The pituitary cell types arise in a temporally and spatially specific pattern as directed by the transcription factors, occurring between week 7 and week 16 of human gestation. If one transcription factor of the developmental series malfunctions or is expressed out of series, as is seen in clinical syndromes of

hypopituitarism (Table 94.1), then a very typical pattern of pituitary hormone deficiency is manifest (Kelberman et al., 2009; Romero et al., 2009).

Each mature pituitary cell type synthesizes and secretes a corresponding hormone that is regulated by a hypothalamic peptide: corticotrophs secrete ACTH in response to CRH; gonadotrophs secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in response to gonadotropin-releasing hormone (GnRH); lactotrophs secrete prolactin in response to dopamine; thyrotrophs secrete thyrotropin (TSH) in response to thyrotropin releasing hormone (TRH); and somatotrophs secrete growth hormone in response to growth hormone-releasing hormone and somatostatin.

The mature pituitary cell types contain secretory granules by 10 to 12 weeks' gestation, and the hormones can be measured by 12 to 17 weeks' gestation (Kelberman et al., 2009). The pituitary portal circulation is mature by 12 to 17 weeks, and thus regulation of pituitary hormone release by the corresponding hypothalamic peptide may be operational by that time. However, the negative feedback mechanisms that finely tune hypothalamic-pituitary-end hormone release may not be fully mature until later in gestation. At birth the negative feedback mechanisms are fully mature, which is crucial in the diagnostic evaluation of infants with suspected pituitary hormone disorders.

The neurohypophysis (posterior pituitary), formed by the evagination of the neuroectoderm, is fully developed by 10 to 12 weeks' gestation and contains granules of arginine vasopressin (AVP)

and oxytocin (Leake and Fisher, 1985). The neurohypophysis comprises the axonal terminals of hypothalamic neurons whose cell bodies are in the mature paraventricular nuclei and supraoptic nuclei. These neurons generate AVP or oxytocin separately and thus are regulated by separate factors. AVP-releasing neurons integrate signals from plasma osmolality sensors and baroreceptors in the carotid sinus and aortic arch to release AVP and thus regulate serum osmolality and systemic blood pressure. AVP acts on the renal collecting duct via V_2 receptors to induce water reabsorption. AVP also acts on V_{1A} receptors on endothelial cells to increase arterial and venous constriction and thus increase blood pressure. Serum osmolality is tightly controlled between 280 and 295 milliosmoles (mOsm)/kg water in adults (Robertson et al., 1976). With even a slight increase in serum osmolality, AVP release increases exponentially to induce renal water reabsorption to a maximum urine osmolality of 800–1200 mOsm/kg water (maximum urine osmolality depends on the osmolality of the upstream kidney medulla). In neonates, however, the urine-concentrating ability of the kidney is impaired to a maximum of 300 mOsm/kg water because of the relative immaturity of the renal tubules rather than lack of AVP release; AVP is present in the fetus and neonate, and V_2 receptors are functional (Baum et al., 1998).

Diseases of Hypothalamic or Pituitary Maldevelopment

Given the overlapping developmental window of important cranial midline structures, a diagnosis of congenital hypopituitarism in a neonate should be considered if there are intracranial or extracranial midline defects. For instance, hypopituitarism has been reported in children with cleft lip or palate or central incisors. Hypopituitarism and diabetes insipidus can be encountered in neonates with holoprosencephaly. Children who have intracranial abnormalities along the spectrum of optic nerve hypoplasia, with or without septo-optic dysplasia, commonly have congenital hypopituitarism.

Neonates with congenital hypopituitarism because of a mutation in a gene important in pituitary differentiation may or may not have obvious defects in midline structures (Table 94.1). In the absence of these clinical signs, hypopituitarism may be suspected in neonates with micropenis and normal testicular descent (caused by growth hormone with or without gonadotropin deficiency), prolonged hypoglycemia (caused by combined growth hormone and cortisol deficiency), or rarely, cholestatic giant cell hepatitis (caused by combined growth hormone, thyroid hormone, and cortisol deficiency). As fetal growth is independent of growth hormone, children with congenital hypopituitarism are of normal size and weight at birth. If a newborn screen uses T_4 levels as the screen for congenital hypothyroidism, then low T_4 levels may be a diagnostic clue; if a newborn screen measures thyrotropin (also known as thyroid stimulating hormone, TSH) to screen a newborn for congenital hypothyroidism, the central hypothyroidism of hypopituitarism will not be detected. After 2 months of life, a clue to optic nerve hypoplasia may be a disconjugate gaze. If diabetes insipidus is diagnosed, then full evaluation of the remaining pituitary hormones is mandatory.

Adrenal Gland Development

Cells of the adrenal cortex arise from the intermediate mesoderm and can be recognized at the upper pole of the mesonephros by 3 to 4 weeks' gestation. Cells of the adrenal medulla are derived

from the ectoderm, and they infiltrate the adrenal cortex cells at 7 to 8 weeks' gestation. Encapsulation of the adrenal gland occurs at 9 weeks' gestation, resulting in the formation of a distinct organ above the developing kidneys. The cortical and medullary cells proliferate rapidly and sort into a central medulla and surrounding cortex (Ishimoto and Jaffe, 2011; Dattani and Gevers, 2016).

The HFA cortex acquires two distinct zones: the inner FZ and the outer definitive zone (DZ). DZ cells are in an undifferentiated proliferative state, whereas FZ cells are differentiated, steroidogenic cells. Current data suggest that the HFA cortex is a dynamic organ in which cells proliferate in the periphery (i.e., the DZ) and migrate centripetally, differentiating to form the inner FZ that is unique to primate gestation (Spencer et al., 1999). There is a third zone between the DZ and FZ, named the *transitional zone* (TZ). Cells in this zone show intermediate characteristics and have the capacity to produce cortisol, being analogous to the zona fasciculata cells of the adult adrenal cortex. By the 30th week of gestation, the HFA cortex manifests a rudimentary form of the adult adrenal cortex; the DZ and TZ begin to resemble the zona glomerulosa and the zona fasciculata, respectively. The third definitive cortical layer, the zona reticularis, is absent at birth and starts developing at 3 years of age to form an extragonadal source of sex steroids. The cells of the inner FZ are the primary site for steroidogenesis during gestation, producing an abundant amount of adrenal androgens, which are the substrates for placental estrogen production.

The weight of the adrenal gland increases 10-fold from 8 to 10 weeks' gestation, and the gland continues to grow rapidly thereafter until term. By 30 weeks, it achieves a relative size 10 to 20 times that of the adult adrenal gland. A further doubling in weight occurs thereafter. Soon after birth, the HFA undergoes rapid involution with rapid disappearance of the FZ and a decrease in androgen secretion. As a consequence, the total weight of the glands decreases by approximately 50%. Remodeling of the postnatal adrenal gland involves a combination of FZ regression and development of the zona glomerulosa and zona fasciculata. During the first year, the fetal cortex regresses, and adrenal mass diminishes to 2–3 g.

The early stages of adrenal development are regulated by a number of transcription factors, mainly steroidogenic factor 1 (SF1) and DAX1 (dosage-sensitive sex reversal, adrenal hypoplasia congenital, X-chromosome factor). SF1-knockout mice manifest adrenal and gonadal agenesis and gonadotropin deficiency (Parker et al., 2002). Inactivating DAX1 mutations are associated with adrenal hypoplasia and gonadotropin deficiency in mice and humans (McCabe, 2007).

ACTH secreted by the fetal pituitary is the primary regulator of the development and function of the HFA. There are other ACTH-independent regulators; these include local peptide growth factors and placenta-derived factors, such as CRH and estrogens. The steroidogenic activity in the HFA is characterized by early transient cortisol biosynthesis (Goto et al., 2006). The hypothalamic–pituitary–adrenal axis is sensitive to glucocorticoid-mediated feedback at this time, and therefore 46,XX females with steroidogenic defects (such as congenital adrenal hyperplasia) who lack cortisol will have an elevated ACTH level that stimulates overproduction of androgens, resulting in virilization of the female genitalia. The cortisol production is suppressed thereafter until late gestation (because of the lack of 3 β -hydroxysteroid dehydrogenase type 2 expression). Near term, the fetal cortisol production rate increases and is similar to that in adults, per unit body weight. There is extensive production of DHEA and its sulfate, precursors of placental estrogen, during most of gestation. This begins at around 8 to 10

weeks' gestation and increases significantly during the second and third trimesters. Aldosterone synthesis in the HFA may be suppressed during midgestation because of the probable lack of *CYP11B2* expression but likely becomes active by term because 80% of aldosterone in human fetal blood at term appears to originate from the HFA.

The adrenal medulla functions as a classic endocrine (ductless) gland that secretes hormones directly into the bloodstream. It also participates in sympathetic control via preganglionic sympathetic nerve fibers. Pheochromocytoblasts give rise to the medullary pheochromocytes, which are epinephrine- and norepinephrine-secreting homologues of sympathetic postganglionic cells. By 3 months' gestation, adrenal pheochromocytes secrete epinephrine and norepinephrine into the medullary sinusoids and then into the systemic circulation (Unsicker et al., 2005). The hypothalamic–pituitary–medullary adrenal axis becomes sufficiently functional by midgestation so that fetal stress responses can be independent of those of the mother (Gitau et al., 2001). This fetal catecholamine stress response contrasts with the fetal cortisol output capacity, which is minimally present before midgestation.

Thyroid Gland Development

Thyroid hormones T_4 and triiodothyronine are essential for the development and maintenance of normal fetal physiologic processes, especially those of the central nervous system, where thyroid hormones assist in brain maturation throughout gestation (Neale et al., 2007). Thyroid hormones regulate genes involved in myelination and neuronal/glial cell differentiation (Bernal, 2005). Delivery of thyroid hormones to the fetal brain is a complex process requiring, at different times, expression of brain thyroid hormone receptors, placental thyroid hormone and iodide transport, a feedback system that involves the hypothalamic–pituitary–thyroid (HPT) axis, and thyroid hormone metabolism by liver and brain deiodinase enzymes (deiodinase type 2 and deiodinase type 3), which ensure basal levels are sustained (Zoeller et al., 2007).

The thyroid is the first endocrine gland to develop in the embryo. It is derived from contributions of two anlagen: a midline thickening of the pharyngeal floor (median anlage) that gives rise to the T_4 -producing follicular cells and paired caudal extensions of the fourth pharyngobranchial pouches (lateral anlagen) that act as the precursor to the parafollicular calcitonin-secreting cells (C cells). The thyroid begins its development by 24 days' gestation when the median anlage forms the thyroid diverticulum that extends from the floor of the buccal cavity to the fourth branchial arch. At 24 to 32 days the median anlage becomes a bilobed structure. By 50 days the median and lateral anlagen have fused and the buccal stalk has ruptured. During this period the thyroid gland migrates caudally from the pharyngeal floor to the developing hyoid bone and laryngeal cartilages, where it reaches its final location in the anterior neck below the thyroid cartilage. During its descent the thyroid gland retains an attachment to the pharynx by a narrow epithelial stalk known as the *thyroglossal duct* that disappears by 7 weeks' gestation. Abnormalities in thyroid descent result in ectopic thyroid, persistent thyroglossal duct, or cyst. The genes involved in thyroid gland development include *HEX*, *TTF1*, *FOXE1*, *NKX2-5*, and *PAX8*. Defects in these genes can result in varied abnormalities in thyroid gland development and congenital hypothyroidism (Kratzsch and Pulzer, 2008).

By 10 to 11 weeks, clusters of endodermal epithelial cells form single layers around lumens, the thyroid follicles, in which colloid begins to appear. At 4 weeks the fetal gland is able to synthesize

thyroglobulin; 6 to 8 weeks later the thyroid synthesizes thyroid hormones mediated by the incorporation of iodine. This early growth and development appears to be independent of TSH, as secretion of TSH cannot be shown before 10 to 12 weeks. As a consequence of maturation of the hypothalamic–pituitary–thyroid axis, TSH levels increase rapidly thereafter. Similarly, total T_4 and free T_4 levels increase significantly in the second and third trimesters. The fetal pituitary–thyroid feedback mechanism appears to be fully responsive by 18–20 weeks. Hypothyroidism will result in elevated fetal TSH production, whereas hyperthyroidism caused by maternal Graves disease (due to transplacental passage of maternal thyroid-stimulating autoantibodies) will cause suppressed TSH production.

Prematurity can result in low thyroid hormone levels, and the severity correlates inversely with the gestational age because of the immaturity of the hypothalamic–pituitary–thyroid system. Fifty percent of preterm infants born before 28 weeks' gestation will have transient hypothyroxinemia of prematurity identified by low T_4 and normal TSH levels that do not require treatment. Very low-birthweight infants are at higher risk of developing primary hypothyroidism and can have a delayed TSH level rise. Thyroid hormone treatment is indicated in these infants, although it can be a transient problem (Dattani and Gevers, 2016).

Small amounts of maternal thyroid hormones cross the placenta, and adequate functioning of both maternal and fetal thyroid glands is important for normal fetal development. In congenital hypothyroidism because of thyroid agenesis (athyreosis), maternal thyroid hormones lessen the impact on fetal neurologic development. Early neonatal diagnosis and T_4 treatment permit normalized growth and development. In contrast, when the mother is hypothyroid throughout gestation, the developmental consequences are more severe (Glinioer and Delange, 2000).

Reproductive Axis Development

Similar to other hypothalamic–pituitary–end gland systems, early gonadal development is completely separate from neuroendocrine development and thus will be discussed separately. GnRH neurons, the hypothalamic neurons that induce gonadotrophs to synthesize and secrete LH and FSH, are unique among hypothalamic neurons in that they arise outside the neuroectoderm in the olfactory pit. This occurs at week 6 after conception. The GnRH neuron begins to synthesize and secrete GnRH shortly thereafter. The neurons then migrate via the forebrain, arriving at the hypothalamus by week 9 (Schwanzel-Fukuda et al., 1996). The location, number of GnRH neurons, and projection to the median eminence are similar to those in adult animals. Migration is supported by the signaling protein products of the genes *ANOS1* (anosmin 1), *PROK1* (prokineticin 1), and *FGF8* (fibroblast growth factor 8), as well as receptor encoding genes such as *FGFR1*, *PROKR2*, and *CHD7* (Bhagavath and Layman, 2007).

Before gestational week 6 the male and female genital duct systems coexist with an indifferent (bipotential) gonad. The specifics of sex-specific gonadal differentiation and associated disorders are discussed in Chapter 97. In brief, the presence or absence of the Y chromosome, and thus the gene *SRY*, is the determining factor directing development of the bipotential gonad into either testes or ovaries. *SRY* is expressed by week 6 of gestation. *SRY* directs the expression of many genes that direct the differentiation of the bipotential gonad into the Leydig (testosterone-producing) cells of the testes as well as the Sertoli cells (Achermann and Hughes, 2016). *SRY* also induces expression of the gene *SF1*. *SF1* in turn

acts to induce expression of anti-müllerian hormone, which induces regression of the female (müllerian) duct structures. Müllerian structures include the fallopian tubes, uterus, and upper third of the vagina. In the presence of two normal X chromosomes, ovarian differentiation commences, although less is known about ovarian development. Formation of the bipotential gonad into testes or ovaries is complete by week 8 of gestation, while differentiation of the genital duct systems into the male or female internal reproductive organs is complete by week 9 of gestation (Achermann and Hughes, 2016).

External development of male or female structures is determined by the presence or absence of testosterone (and thus the *SRY* gene). Further conversion of testosterone to dihydrotestosterone (DHT) is necessary for normal development of the penis and prostate gland. In the absence of DHT, the lower two-thirds of the vagina and the labia minora and majora develop. Placental human chorionic gonadotropin directs testosterone secretion by the ever-expanding Leydig cell population after week 14 of gestation. The testosterone formed in effect directs formation of the external genitalia. LH and FSH reach peak levels at midgestation, about 20 to 24 weeks. The testes and ovaries are responsive to LH and FSH by week 20, and some primary follicles are seen in the ovaries. However, placental estrogen predominates, so estrogen secretion by the fetal ovary is thought to be minimal. LH-directed testosterone synthesis is required for normal testicular descent from the abdomen into the scrotal sac in late gestation as well as for further lengthening the penis in late gestation. By the last half of the third trimester, placental estrogen production provides negative feedback to the axis to cause LH and FSH levels to decrease (Kaplan et al., 1976).

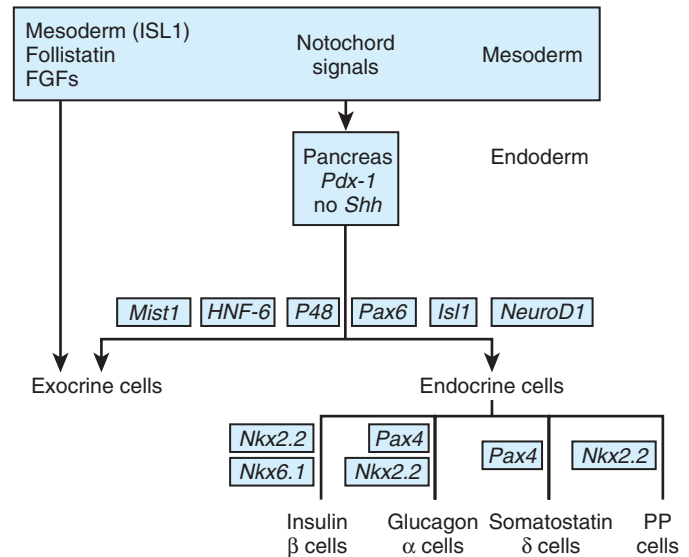

Development of the Endocrine Pancreas

The pancreas is derived from two buds, dorsal and ventral, that arise from the distal foregut endoderm. It contains a distinctive combination of cell lineages. The exocrine tissue comprises acinar cells that secrete digestive fluid and a duct system by which the fluid drains into the intestine. The endocrine part is arranged as discrete islets of Langerhans, which contain distinct cell types secreting different hormones into the circulation (α cells, glucagon; β cells, insulin; δ cells, somatostatin; ϵ cells, ghrelin; and γ cells, pancreatic polypeptide) (Jennings et al., 2015).

Human pancreas formation is first evident at 26 days' gestation, and it begins with the dorsal bud formation, which is followed by the appearance of two ventral buds at 30 days. The left ventral bud gradually regresses, whereas the right ventral bud migrates posteriorly and fuses with the dorsal bud on gut rotation at 6 to 7 weeks' gestation. Failure of the left ventral bud to regress could lead to an annular pancreas. The dorsal pancreas gives rise to most of the pancreas, including the upper part of the head, the isthmus, the body, and the tail of the pancreas. The right ventral bud gives rise to the inferior part of the head (Pan and Brissova, 2014).

Starting from day 45 to day 47 of gestation, the pancreatic epithelium undergoes active growth and branching morphogenesis to give rise to endocrine and acinar cells under the influence of locally acting signals and activation of lineage-specific transcription factors (Peters et al., 2000). During this process, pancreatic epithelium is embedded in the loose mesenchyme and is surrounded by a dense peripancreatic mesenchyme. At approximately 7 to 8 weeks the epithelium begins to ramify and starts to form a lobular pattern (Pan and Brissova, 2014).

The first endocrine cells that appear are insulin-expressing cells at 7.5 weeks, and they remain the most prevalent endocrine cell

• **Fig. 94.3** Molecular Control of Cell Fate Choices in the Pancreas. *Pax6* and *Isl1* are expressed early, and their disruption leads to the reduction or absence of endocrine differentiation, which suggests that they could be expressed in endocrine progenitors able to give rise to all cell types. In *Isl1*-mutant mice, *Pax6* is not expressed, which suggests *Pax6* is downstream of *Isl1*. Although *Pax4*, *NeuroD1*, *Nkx2.2*, and *Nkx6.1* are expressed as early as *Pax6* and *Isl1*, they affect the differentiation of only a subset of lineages. *Pax4* is required for glucagon-producing and somatostatin-producing cell differentiation. *Nkx2.2* is expressed in all islet cells, except somatostatin-producing cells, and its inactivation leads to the absence of the cell types where it is expressed. *Nkx6.1* is itself required for insulin cell differentiation. Although *Mist1* and *Onecut1* (also known as *Hnf6*) are expressed in endocrine cell lineages, their function has not yet been assessed by inactivation experiments. *FGFs*, Fibroblast growth factors; *PP*, pancreatic polypeptide. (From Grapin-Botton A, Melton DA. Endoderm development: from patterning to organogenesis, *Trends Genet.* 2000;16:124–130.)

type during the first trimester (Piper et al., 2004). This is followed by the appearance of glucagon- and somatostatin-expressing cells at week 8 and pancreatic polypeptide-expressing and ghrelin-expressing cells at week 9. Ongoing β -cell proliferation and differentiation are dependent on insulin-like growth factor type 2 (*IGF2*) expression. Islet formation begins by week 12. Islet volume increases from about 4% to 13% of total pancreatic tissue by term (Peters et al., 2000). Targeted gene deletion studies in mice have demonstrated critical roles for several transcription factors in pancreatic endocrine development (Fig. 94.3).

Neonatal insulin kinetics and end-organ sensitivity to insulin appear to be established during the third trimester in preparation for extrauterine fuel metabolism. The maternal environment and fetal genome appear to influence the number and/or function of pancreatic β cells in early life, with lifelong implications for postnatal diabetes. In contrast, insulin gene-knockout mice and human newborns with pancreatic agenesis experience severe intrauterine growth restriction (IUGR), consistent with insulin's role in mitogenesis and growth.

Development of the Parathyroid Glands and Fetal Mineral Homeostasis

The parathyroid glands arise from the third and fourth pharyngeal pouches. The third pouches develop into the inferior parathyroid

glands, and the fourth pouches develop into the superior glands. Fetal parathyroid glands produce low amounts of parathyroid hormone (PTH) throughout gestation that can be detected as of 10 weeks. It is unclear if they also make PTH-related protein (PTHrP), which is mainly produced in the placenta. Other hormones involved in mineral homeostasis include calcitonin, which is detectable in fetal thyroidal C cells as early as 14 weeks. The fetal renal tubules can synthesize the active form of vitamin D, 1,25-dihydroxyvitamin D (calcitriol), as early as the second half of gestation, but the fetal levels remain low.

Mineral and bone metabolism is regulated differently in utero compared with the adult. The placenta meets the fetal mineral need by actively transporting calcium, phosphorus, and magnesium from the maternal circulation to maintain higher fetal concentrations compared with maternal levels. These high levels are necessary for the developing skeleton to accrete a normal amount of mineral by term. A human fetus typically accumulates approximately 30 g of calcium by term, with 80% of that mineral content obtained in the third trimester.

PTH and PTHrP are critical for fetal bone development, regulation of serum minerals, and placental mineral transfer, while calcitriol and calcitonin are not required. PTH and calcitriol circulate at low concentrations in the fetal circulation. PTH is suppressed by the high fetal serum calcium level. Low calcitriol concentration is caused by low PTH concentration, high calcium concentration, and rapid clearance (Kovacs, 2014).

Hormonal Regulation of Fetal Growth

Hormones that play an important role in postnatal growth, such as thyroid hormone, growth hormone, and gonadal steroids, play a very limited role in fetal growth. As such, neonates with these hormonal disorders are generally born with normal weight and size. Fetal growth is driven by nutritionally dependent growth factors such as insulin, or other growth factor systems such as IGF1, IGF2, and the epidermal growth factor (EGF)–transforming growth factor (TGF) system.

Insulin

Insulin is an important fetal growth factor, as evident by the hyperinsulinemia and macrosomia experienced by infants born to women with uncontrolled diabetes mellitus. In contrast, infants with pituitary agenesis and corresponding lack of insulin are small at birth, with minimal muscle bulk and adipose tissue (Schwitzgebel et al., 2003).

Insulin-Like Growth Factor 1

The importance of IGF-1 in fetal growth is derived from studies of humans and mice with *IGF1* or IGF-1 receptor (*IGF1R*) mutations. Humans with mutations in these genes have IUGR, microcephaly, hypoglycemia, and severe developmental delay (Cooke et al., 2016). Mice null for the *IGF1* gene or the *IGF1R* gene are 60% of normal weight and die shortly after birth because of impaired lung maturation.

Insulin-Like Growth Factor 2

The importance of IGF-2 to fetal somatic and organ growth is manifest by the phenotypes of Beckwith–Wiedemann syndrome (BWS) and Russell–Silver syndrome (RSS). The *IGF2* gene is

normally imprinted, such that only the paternal allele is active. In BWS, there is either loss of imprinting, such that the maternal allele is also active, or there are two copies of the active, paternal allele (uniparental disomy). Infants with BWS have *IGF2* overexpression and have resultant fetal and postnatal overgrowth. This overgrowth is manifest as macrosomia, enlarged tongue, β -cell hypertrophy with hyperinsulinemic hypoglycemia, and an increased risk of certain childhood cancers. In contrast, RSS may be due to duplication of the maternal allele or silencing of the paternal allele via imprinting. These infants have IUGR with postnatal growth retardation, with adult height -4 standard deviations from the mean (Cooke et al., 2016). Other clues to the diagnosis of RSS include hemihypertrophy, clinodactyly, triangular facies, and normal head circumference.

Epidermal Growth Factor–Transforming Growth Factor System

The role for the EGF–TGF system in fetal and somatic growth is derived from rodent studies and in vitro studies. EGF and TGF have 40% homology in amino acid structure to each other and can bind each other's receptor. EGF, TGF, and their receptors are expressed in all mammalian tissues studied, including placenta, and the expression increases with gestation in fetal rodents and humans. In vitro, treatment with EGF or TGF induces neuronal cell proliferation as well as placental cell proliferation. Embryos of mice null for EGF/TGF or the receptors are smaller than wild-type embryos (Dattani and Gevers, 2016). In late gestation, they have maldeveloped midbrain, hindbrain, and ventral forebrain.

Placental Factors

Human placental lactogen is a major regulator of maternal glucose, amino acid, and lipid metabolism during pregnancy, allowing mobilization of these fuel sources for use by the fetus (Newbern and Freemark, 2011). Alterations in maternal nutrition induced by starvation or disease also affect fetal growth. Uterine vasoconstriction or vascular insufficiency of the placenta is also associated with poor fetal growth and neonatal IUGR. Vascular compromise of the placenta may be due to maternal hypertension, drug exposure, infection, or placental abruption.

Developmental Origin of Health and Disease

The developmental origin of health and disease hypothesis is the theory that the perinatal environment (conception to infancy into toddlerhood) directly influences the development of metabolic and cardiovascular disease during adulthood. This hypothesis, also termed the *Barker hypothesis*, was first proposed in the 1990s by David Barker as he attempted to account for the higher rates of heart disease in poorer areas of Britain (Barker, 2007). He noted that the geographic areas with higher heart disease rates had higher rates of neonatal deaths in previous decades even accounting for differences in smoking rates. Using longitudinal data from the 15 boroughs of London, he found that the boroughs with the highest neonatal mortality in 1910s to 1925 also had the highest rates of cardiovascular disease. Delving into birthweight data, Barker found low birthweight was associated with an increased risk of death from coronary heart disease. Many studies since Barker's original studies have replicated his results in men and women in Europe, North America, South America, and India. In addition to heart disease, low birthweight has been associated with increased risk

of type 2 diabetes, cerebrovascular disease, hypertension, dyslipidemia, altered puberty, and obesity in adulthood.

The association of low birthweight with metabolic disease led to the proposal that a nutrient supply perceived as limited by the fetus yields a fetal/neonatal “thrifty phenotype” that would allow survival in a nutrient-limited extrauterine environment (Hales and Barker, 2001). The “programming” for an extrauterine life of limited nutrients proves maladaptive in the abundant postnatal nutrition environment. As a corollary to low birthweight, epidemiologic studies have now found that excess maternal weight during pregnancy or excessive weight gain in early infancy (whether experienced by low-birthweight or normal-weight neonates) is also associated with increased risk of metabolic diseases later in life. At highest risk of metabolic disease as adults are individuals with low birthweight and excessive weight gain in infancy and childhood.

Other in utero exposures that have been associated with development of adult disease include increased risk of obesity and mental disorders in offspring of pregnancies complicated by maternal depression, increased risk of metabolic disorders in offspring of mothers with hyperandrogenemia, and increased risk of hypertension in offspring of pregnancies complicated by preeclampsia (Padmanabhan et al., 2016). Emerging epidemiologic data suggest that perinatal exposure to certain endocrine disrupting chemicals (EDCs) is associated with obesity, metabolic disease, cancer, and reproductive defects in offspring. EDCs are chemicals that mimic hormone actions and thus could change maternal, placental, and fetal hormonal milieus. EDCs are categorized into persistent organic pollutants (POPs), which linger in the environment for decades, or short-lived pollutants used in manufacturing. Examples of POPs include organochlorine pesticides such as dichlorodiphenyltrichloroethane, industrial by-products such as polychlorinated biphenyls, and flame retardants such as polybrominated diphenyl ethers. Examples of short-lived pollutants include phthalates and bisphenols, used in plastics and adhesives. EDCs are ubiquitous in the environment, accounting for daily exposure to minuscule amounts. EDC doses and developmental exposure windows that are disease causing are under dispute for many of the EDCs. Controlled exposure studies that would provide a causal relationship between EDC

exposure and human disease are not ethically feasible, and thus disease risk must be surmised from the body of evidence provided by epidemiologic and animal exposure studies.

A number of mechanisms have been proposed to program later disease by environmental influences. These include epigenetic regulation of gene expression; oxidative stress of tissues resulting in damage to DNA, lipids, and proteins; and direct hormonal effects on development. Epigenetic changes that affect gene expression include DNA methylation, histone modification, chromatin packing, and micro-ribonucleic acid expression. These changes are malleable or permanent and can accumulate over time to influence gene expression in the short term or long term. Oxidative stress may lead to inflammation of tissues and chronic maladaptation (Padmanabhan et al., 2016). Finally, an example of direct hormonal effects on development is the direct effect of intrauterine testosterone on gonadal development and, in females, later development of obesity.

Disorders of Calcium and Phosphorus Metabolism

ILDIKO H. KOVES, KATHRYN D. NESS, ANGEL SIU-YING NIP, AND PARISA SALEHI

KEY POINTS

- Neonatal hypercalcemia may be asymptomatic if there are only mild elevations in calcium level or may lead to severe symptoms such as failure to thrive, polyuria, lethargy, and seizures.
- The causes of hypercalcemia can differ but are due to dysregulation of calcium regulatory systems.
- Treatment of hypercalcemia includes hydration and diuretics, with the use of other agents such as glucocorticoids, calcitonin, calcimimetics, and bisphosphonates in severe cases.
- Metabolic bone disease of prematurity is caused by deficiencies in dietary phosphate and calcium, early withdrawal of placental estradiol and progesterone, lack of mobility, and therapy with medications that can increase urinary calcium excretion and contribute to serum mineral imbalance and osteopenia.
- Osteopenia in preterm infants usually appears between 6 and 12 weeks of age, and fractures may be seen. The incidence and severity increase with decreasing gestational age and birthweight and are more common in preterm infants having a complicated medical course and delayed nutrition.

Homeostatic Control of Calcium and Magnesium

Calcium plays two important physiologic roles. Calcium salts in bone provide structural integrity. Calcium ions present in the cytosol and extracellular fluid (ECF) are essential for maintenance and control of many biological processes, including cell–cell communication, cell aggregation and division, coagulation, neuromuscular excitability, membrane integrity and permeability, enzyme activity, and secretion. This functional diversity is made possible by the maintenance of a large electrochemical gradient between the ECF ionized calcium (Ca^{2+}) concentration, which is in the 1-mmol/L range, and the resting intracellular (cytosolic) Ca^{2+} concentration, which is about 0.1 $\mu\text{mol/L}$.

Significant alterations in serum calcium concentration occur frequently in the neonatal period. It is important to evaluate these potential derangements in light of normal dynamic changes that

occur during the perinatal transition. After the first 2 to 3 days, normal total serum calcium concentrations vary only slightly with age and a range between 8.8 and 10.6 mg/dL (2.2–2.6 mmol/L), with an ionized serum calcium concentration of 4 to 5.6 mg/dL (1–1.4 mmol/L). The metric measure unit conversion factors are 0.2595 and 0.2495, respectively, as used everywhere other than the United States.

Approximately 55%–60% of the total plasma calcium is diffusible (or ultrafilterable), the remainder being protein bound. Most diffusible calcium is ionized, but about 5% of total circulating calcium is complexed to plasma anions, such as phosphates, citrate, and bicarbonate. Ca^{2+} is the only biologically available fraction of ECF calcium. It is subject to precise metabolic control based on the integrated regulation of calcium fluxes with respect to the intestine, kidneys, and bone. The precise regulation of circulating Ca^{2+} is controlled by calcium itself, through a calcium receptor and several hormones, the most important of which are parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D ($1,25[\text{OH}]_2\text{D}$) (Carmeliet et al., 2003; Ramasamy, 2008; Allgrove and Shaw, 2009).

Hypoalbuminemia leads to a decline in total serum calcium, but proportionate increases in the ionized fraction usually maintain serum Ca^{2+} concentration within the normal range. Acute alkalosis (e.g., hyperventilation or bicarbonate infusion) or rapid administration of citrate-buffered blood (e.g., during exchange transfusion, initiation of extracorporeal membrane oxygenation [ECMO], cardioplegia, or organ transplant) may acutely lower serum Ca^{2+} concentration by increasing albumin binding or citrate chelation. These conditions can produce transient clinical manifestations of hypocalcemia but do not lower the total serum calcium concentration (Clase et al., 2000). Generally, for routine clinical purposes, measurement of total serum calcium concentration often suffices, and the correction formula in the setting of hypoalbuminemia for total serum calcium concentration measured as mg/dL is:

$$\begin{aligned} \text{Corrected Ca Level} \\ = [0.8 \times (\text{Normal Albumin Level} - \text{Patient's Albumin Level})] \\ + \text{Serum Ca Level} \end{aligned}$$

Large amounts of calcium exchange occurs in kidney, bone, and intestine. Although the intestine has considerable calcium absorptive capacity, renal tubular calcium reabsorption usually exceeds intestinal

absorption by at least 40-fold. Most of the tubular Ca^{2+} load is reabsorbed in the proximal tubule and thick ascending limb of the loop of Henle via paracellular, passive flux (coupled with sodium reabsorption) driven by the existing electrochemical gradient. A transcellular pathway in the distal nephron tightly regulates the rest of urinary Ca^{2+} reabsorption. Calcitropic hormones regulate the distal Ca^{2+} -selective, Na^+ -independent channels. More than 98% of total body calcium is deposited in the skeleton as hydroxyapatite ($\text{Ca}_5[\text{OH}][\text{PO}_4]_3$); the ECF and soft tissues contain the remainder. A small fraction of skeletal calcium freely exchanges with the ECF and serves as an important buffer of circulating calcium. Consequently, decreased skeletal calcium is a hallmark of most metabolic bone diseases.

Magnesium homeostasis is largely mediated through the kidneys. Approximately 80% of total plasma magnesium is filtered through the glomerulus and is reabsorbed mainly in cortical segments of the thick ascending limb of the loop of Henle. Once the maximal tubular reabsorption is exceeded, filtered magnesium is excreted into the urine. Hormones regulate magnesium reabsorption by changing the transepithelial voltage and paracellular permeability of tubular cells. Magnesium is required to maintain normal PTH secretory responses.

Homeostatic Control of Phosphorus

Blood inorganic phosphate concentration varies with age. It is highest during infancy and gradually declines to adulthood. Approximately 10% of plasma inorganic phosphate is noncovalently bound to protein, whereas 90% circulates as ions or as complexes with sodium, calcium, or magnesium. About 80%–85% of total body phosphorus contributes to mechanical support as part of the hydroxyapatite lattice of bone. The remainder is distributed in the ECF, largely as inorganic ions or complexes, and in soft tissues as phosphate esters. Intracellular phosphate esters and phosphorylated intermediates regulate cell metabolism and gene expression (via phosphorylase, kinase, and phosphatase activities) and generate and transfer cellular energy (i.e., via adenosine triphosphate). Cytosolic and ECF phosphorus levels (approximately 0.1 and 0.2 mmol/L, equivalent to 0.31 and 0.62 mg/dL respectively) are less stringently regulated than are levels of Ca^{2+} and magnesium (Mg^{2+}).

Dietary phosphate is generally absorbed in proportion to its content in food. Although phosphorus and calcium can be absorbed along the entire length of the small intestine, most phosphate absorption occurs in the jejunum and ileum, whereas most calcium absorption occurs in the duodenum. The renal proximal tubule is the principal regulatory site for phosphorus homeostasis (Silver and Naveh-Many, 2009). Renal regulation is accomplished primarily by variation of the threshold for phosphate reabsorption (the tubular maximum for inorganic phosphate [TmP]/glomerular filtration rate [GFR]). Hormones (PTH, PTH-related protein [PTHrP], growth hormone) and dietary phosphate reset this theoretical threshold by regulating apical tubular Na^+ - TmP cotransporters (Murer and Biber, 1995). Essentially, TmP/GFR is the “setpoint” that defines the fasting serum phosphorus concentration. At lower serum phosphorus levels, most filtered phosphorus is reabsorbed; at higher levels, most filtered phosphorus is excreted. To assess TmP/GFR , a fasting urine specimen is obtained for measurement of phosphorus and creatinine along with simultaneous determination of serum phosphorus and creatinine. A nomogram has been constructed so that TmP/GFR can easily be derived from these values (Walton and Bijvoet, 1975).

The higher serum phosphate levels in infants (e.g., 4.5–9.3 mg/dL) compared with those in adults (3.0–4.5 mg/dL) reflect infants’ greater tubular phosphate resorption. This adaptation permits avid tubular phosphate conservation despite high ambient serum phosphate levels. For this reason, neonatal disorders of chronic hypophosphatemia and/or phosphorus depletion usually result from inadequate dietary supply (as in preterm infants) or intrinsic (e.g., familial hypophosphatemic rickets) or extrinsic (e.g., hyperparathyroidism) alterations in TmP/GFR . Similarly, chronic hyperphosphatemia usually implies either intrinsic (e.g., renal insufficiency) or extrinsic (e.g., hypoparathyroidism) abnormalities in TmP/GFR .

Parathyroid–Renal Hormonal Axis

In mammals, calcium and phosphate homeostasis is controlled by a parathyroid–renal hormonal axis involving PTH and $1,25(\text{OH})_2\text{D}$. The influence of these two hormones on bone deposition, mobilization of mineral, and regulation of intestinal and renal absorption is depicted in Fig. 95.1. Deficiency or excess of either hormone causes hypocalcemia or hypercalcemia, respectively.

Parathyroid Hormones

PTH mobilizes calcium and phosphorus from bone, stimulates calcium reabsorption in kidneys, inhibits phosphorus reabsorption by reducing TmP/GFR , and stimulates the renal synthesis of $1,25(\text{OH})_2\text{D}$, which participates with PTH in calcium reabsorption in kidneys, increases the efficiency of intestinal absorption of calcium and phosphorus, and mobilizes calcium from bones. Therefore PTH secretion causes the serum calcium concentration to rise and the serum phosphorus concentration to be maintained or decline.

PTH is a 9500-Da, single-chain polypeptide. It is synthesized by the four parathyroid glands embedded within the thyroid gland poles, which are derived from the embryonic third and fourth pharyngeal pouches. The messenger ribonucleic acid (mRNA) for PTH (preproPTH) encodes the 84 amino acids of the mature peptide, an amino-terminal (N-terminal) “pre” sequence of 25 amino acids, and a basic “pro” hexapeptide, which is clipped intracellularly. After secretion, the intact PTH molecule, PTH (1–84), is further metabolized and rapidly cleared from the circulation, with a half-life of less than 4 minutes. The N-terminal region of the PTH molecule, PTH(1–34), binds the PTH receptor and shows full biological activity, whereas the carboxyl terminal (C terminal) has specific, albeit poorly understood, activities in osteoclasts and osteoclastic precursors.

Secretion of PTH fragments by the parathyroid glands and prolonged clearance of the C-terminal PTH metabolites add considerable immunoheterogeneity to circulating PTH. The numerous inconsistencies found in reports on PTH pathophysiology until the late 1980s are due to use of earlier generation “C-terminal” and “midmolecule” PTH assays. In contrast, current two-site “intact PTH” assays are sufficiently sensitive and specific to detect physiologic levels of biologically active PTH(1–84) and to distinguish hypoparathyroid from euparathyroid states. The normal circulating levels of intact PTH range from approximately 10 to 60 picogram (pg)/mL; the maximally stimulated (hypocalcemic) and maximally suppressed (hypercalcemic) levels for normal parathyroid function are about 100 to 150 pg/mL and 2 to 5 pg/mL, respectively.

Parathyroid cells are exquisitely responsive to changes in ambient Ca^{2+} concentration. PTH secretion may be described as an inverse sigmoid hysteretic relationship between serum PTH and Ca^{2+} with

TABLE 95.1 Other Hormones

| | Serum Calcium Concentration | Intestinal Calcium Absorption | Renal Calcium Excretion | Bone Effects |
|------------------------------|-----------------------------|-------------------------------|-------------------------|---------------------------|
| Glucocorticoids | Increase | Decrease | Increase | |
| Growth hormone | | Increase | | |
| Insulin-like growth factor 1 | | | | Protein synthesis in bone |
| Insulin | | | | Bone loss |
| Thyroid hormone excess | Increase | | Increase | Osteoporosis |

or provitamin D, the immediate precursor of cholesterol, to form a sterol, previtamin D. Previtamin D in the skin undergoes isomerization to the biologically inert vitamin D. Vitamin D enters the circulation bound to vitamin D-binding protein and is transported to the liver, where a mitochondrial cytochrome P450 vitamin D 25-hydroxylase produces 25(OH)D. 25(OH)D (provitamin D) is the major circulating vitamin D metabolite. Because activity of hepatic 25-hydroxylase is not tightly regulated, measurement of serum 25(OH)D is a useful assessment of vitamin D stores. In renal proximal tubule cells, mitochondrial 25(OH)D 1 α -hydroxylase metabolizes 25(OH)D to the biologically active hormone, 1,25(OH)₂D. The normal circulating level of 25(OH)D is approximately 10 to 50 ng/mL. The normal circulating concentration of 1,25(OH)₂D ranges from 30 to 75 pg/mL, or about 1/1000 that of 25(OH)D.

Serum 25(OH)D levels are increased by sunlight exposure and by vitamin D ingestion and are decreased in vitamin D deficiency and in hepatobiliary disorders. Circulating 1,25(OH)₂D levels are increased by hyperparathyroidism and phosphate depletion and are reduced in hypoparathyroidism. 1,25(OH)₂D is biologically inactivated through a series of reactions beginning with 24-hydroxylation. 1,25(OH)₂D induces the 24-hydroxylase in vitamin D target cells. Hypocalcemia, by increasing PTH levels, suppresses this enzyme. 24-Hydroxylase metabolizes 25(OH)D as well as 1,25(OH)₂D. In vitamin D-sufficient states, the kidney preferentially 24-hydroxylates the prohormone, 25(OH)D, to 24,25-dihydroxyvitamin D (24,25[OH]₂D). In contrast, when vitamin D action is required, 25(OH)D 1 α -hydroxylase is preferentially activated for 1,25(OH)₂D synthesis.

The parathyroid-renal (PTH-1,25[OH]₂D) axis, reminiscent of the hypothalamic-pituitary-adrenal axis, is the principal means for systemic response to a sustained or major hypocalcemic challenge. In this long-loop feedback system, 1,25(OH)₂D-mediated calcium absorption provides the ultimate feedback on PTH secretion. PTH secreted in response to hypocalcemia is the principal regulator of renal production of 1,25(OH)₂D, which, in turn, feeds back to suppress PTH gene expression (see Fig. 95.1). Hypocalcemia directly stimulates PTH mRNA transcription. PTH regulates minute-to-minute perturbations of ECF Ca²⁺ concentration. Maximal adjustments of intestinal calcium absorption via the PTH-1,25(OH)₂D axis require 1 to 2 days to become fully operative, so 1,25(OH)₂D effects come into play only when a hypocalcemic stress persists.

Calcitonin

Calcitonin, a peptide hormone synthesized by thyroid parafollicular C cells (also known as *clear cells*) has an antihypercalcemic

effect—that is, opposite that of PTH. Human calcitonin is a 32-amino-acid chain with a 1,7-disulfide bridge and a C-terminal prolinamide. Alternative splicing of several transcripts from the calcitonin gene produces several polypeptide products, some of which have uncertain calcitropic importance. The primary stimulus for calcitonin secretion is a rise in circulating calcium concentration. Calcitonin lowers serum calcium and phosphorus concentrations mainly by inhibiting bone resorption and by increasing calcium excretion in the kidneys (Table 95.1).

Glucocorticoids lower serum calcium concentration by inhibiting osteoclast formation and activity, but use for a long time causes osteoporosis by decreasing bone formation and increasing bone resorption. They also decrease intestinal absorption and increase renal excretion of calcium and phosphorus. Because of these mechanisms glucocorticoids depress hypercalcemia in vitamin D intoxication and subcutaneous fat necrosis.

Growth hormone increases calcium excretion in the kidney and intestinal absorption. Insulin-like growth factor 1, generated by growth hormone action, stimulates protein synthesis in bone. Insulin increases bone formation, with observed bone loss in patients with uncontrolled diabetes mellitus.

Thyroid hormone excess has been described to be associated with hypercalcemia, hypercalciuria, and osteoporosis. The mechanism of these findings is not entirely clear.

Currently, there is no compelling evidence that the calcitonin-like calcium-lowering hormones are critical regulators of calcium homeostasis in nonpregnant adult humans, perhaps because the low prevailing rate of bone turnover blunts the impact of the antiresorptive actions. However, calcitonin may have important calcitropic functions in pregnant and lactating women and in the fetus and neonate, and in other mammals, particularly rodents, whose bones are constantly growing. In human newborns the parafollicular C-cell population and serum calcitonin concentrations are much greater than in adults.

Perinatal Mineral Metabolism

During human pregnancy, approximately 30 g of calcium and more than 16 g of phosphorus are transferred transplacentally from the maternal circulation to the growing fetus during the third trimester, when fetal calcium accretion is approximately 140 to 150 mg/kg per day. In humans a doubling of maternal intestinal calcium absorption and a net increase of calcium accretion into bone compensate for the formidable demand on maternal calcium (Prentice, 2000). A midmolecule PTHrP hormone (Kovacs et al., 1996) expressed principally by the placenta regulates this transplacental calcium pump. TRPV6, a member of the transient receptor

potential channel superfamily, may be the primary calcium channel at the trophoblast apical membrane. Calcium flux across the placenta in *Trpv6*-null mice is reduced by approximately 40% (Suzuki et al., 2008).

Pregnancy

Pregnancy constitutes a unique hormonal milieu that promotes a state of “physiologic absorptive hypercalciuria” (Gertner et al., 1986). Maternal total serum calcium concentration declines slightly during pregnancy, reaches a nadir in the middle of the third trimester, and then increases slightly toward term. The maternal serum phosphorus and magnesium profiles are similar to that of calcium. Maternal serum 25(OH)₂D concentration varies seasonally and with vitamin D intake, but the vitamin D transport protein concentration increases during pregnancy. Serum 1,25(OH)₂D concentrations increase early in pregnancy and continue to rise throughout gestation (Seely et al., 1997). The calculated concentration of free 1,25(OH)₂D also rises. For many years it was believed that PTH levels also increased steadily throughout pregnancy. However, use of newer immunometric “sandwich” assays indicate that PTH concentration actually declines during pregnancy (Davis et al., 1988; Saggese et al., 1991; Seely et al., 1997). PTHrP levels, in contrast, may be higher in pregnant women than in nonpregnant women (Bertelloni et al., 1994). The role of circulating calcitonin in pregnancy is uncertain.

1,25(OH)₂D drives enhanced maternal intestinal mineral absorption (reviewed in Kovacs, 2008). After parturition, 1,25(OH)₂D concentrations and calcium absorption rates (Kent et al., 1991) fall to prepregnancy levels. The interplay of calcitropic and progestational hormones in pregnancy protects the maternal skeleton from demineralization. In contrast, during the relatively low estrogen state of lactation, calcium is mobilized from bone stores, possibly under the influence of PTHrP (Dobnig et al., 1995).

In the third trimester, fetal plasma total and ionized calcium and phosphorus levels are higher than maternal levels, producing a state of “physiologic fetal hypercalcemia” (Rubin et al., 1991). Fetal plasma PTH concentration is low, and calcitonin and PTHrP levels are relatively high. Even these low circulating PTH levels may be functionally important in fetal calcium and magnesium metabolism. There is also a close correlation between maternal and fetal serum 25(OH)₂D levels, consistent with transplacental transfer of this metabolite. Hypocalcemia is commonly found in infants born to women with low circulating 25(OH)₂D levels resulting from poor dietary intake of vitamin D and lack of sunlight exposure. Fetal plasma 1,25(OH)₂D concentration is also relatively low, despite robust renal 25(OH)₂D 1 α -hydroxylase activity, whereas the concentrations of 24,25(OH)₂D are high. The major function of the fetal kidneys in calcium homeostasis may be production of 1,25(OH)₂D rather than renal tubular regulation of calcium excretion. The high circulating concentrations of calcitonin may support this stimulated fetal 25(OH)₂D 1 α -hydroxylase activity. In contrast, the relatively low circulating fetal 1,25(OH)₂D concentrations are a consequence of enhanced placental clearance (Ross et al., 1989). Constitutively activated placental 24-hydroxylase activity (Rubin et al., 1993) also preferentially hydroxylates maternally derived 25(OH)₂D to 24,25(OH)₂D. This placental capacity to metabolize 25(OH)₂D and 1,25(OH)₂D accounts for the enhanced clearance of fetal 1,25(OH)₂D, limits access of placenta-synthesized 1,25(OH)₂D to the fetal and maternal circulations, and, in effect, partitions the maternal and fetal vitamin D pools.

The Neonate

Placental transfer of calcium ceases abruptly at birth. In healthy term newborns, total calcium concentration and Ca²⁺ concentration decline from nearly 11 mg/dL and 6 mg/dL, respectively, in umbilical cord blood to serum levels of 8 to 9 mg/dL and 5 mg/dL, respectively, by 24 to 48 hours. The nadir of Ca²⁺ concentration may range from 4.4 to 5.4 mg/dL. Concomitant rises in the concentrations of PTH and 1,25(OH)₂D stabilize serum calcium concentration as the newborn adapts to extrauterine mineral homeostasis and dietary calcium intake. In preterm infants, calcium absorption from the intestine is nonsaturable and may be vitamin D independent (Bronner et al., 1992). Serum calcitonin levels increase sharply during the first day and remain elevated compared with those in adults. In the mother, prolactin helps stimulate PTHrP expression in lactating breast tissue. PTHrP is secreted into milk at concentrations 10,000-fold higher than in serum. It is possible that the abundant milk PTHrP content ingested by the neonate is important for mineral regulation. By 2 weeks of life, serum calcium concentration rises to the mean values observed in older children and adults.

During the first week of life, urinary phosphate excretion is significantly higher in preterm newborns than in term newborns but then approximates that of term newborns, possibly owing to accelerated postnatal renal maturation. Calcium excretion is low during the first week, when the newborn must compensate for the postpartum fall in serum calcium concentration. After the first several days, calcium excretion increases with a magnitude inversely proportional to gestation. The high urinary calcium-to-creatinine ratio (UCa/Cr) of young infants then steadily declines with age (Sargent et al., 1993). However, in preterm breastfed infants who are more than 2 weeks old, the UCa/Cr can exceed 2.0 (Karlen et al., 1985). These changes may reflect the relative phosphate deficiency in many preterm infants, which results in an adaptively low urinary phosphate excretion, decreased bone mineralization, and, consequently, relatively high urinary calcium excretion.

Key points:

- Onset of neonatal hypocalcemia can present early or late during the neonatal period and depends on the underlying causes.
- Neonatal hypocalcemia may be asymptomatic if mild but may lead to severe symptoms such as hypotonia, seizures, or cardiac arrhythmia.
- Treatment of hypocalcemia includes intravenous or oral calcium supplement depending on the severity.

Neonatal Hypocalcemia

The definition of hypocalcemia depends on gestational age and birthweight. A precise definition of hypocalcemia, like hypoglycemia, in preterm infants is particularly difficult to formulate. Neonatal hypocalcemia has been defined as a serum calcium level below 8 mg/dL (2 mmol/L) in term infants or below 7 mg/dL (1.75 mmol/L) in preterm infants. It is also defined as a Ca²⁺ level less than 3.0 to 4.4 mg/dL (<0.75 to 1.10 mmol/L) (Jain et al., 2010). Under conditions of normal acid–base status and normal serum albumin concentration, serum total calcium and Ca²⁺ levels are linearly correlated, so total serum calcium measurements remain useful as a screening test. However, because Ca²⁺ is the physiologically active fraction, in sick infants it may be preferable to assay Ca²⁺ directly in freshly obtained blood samples. The causes of neonatal hypocalcemia are classified by the timing of onset. Early hypocalcemia occurs in the first 2 to 3 days of life. “Early” and

• BOX 95.1 Causes of Neonatal Hypocalcemia**Early-Onset Hypocalcemia (<48 Hours of Age)**

- Prematurity
- Perinatal distress/asphyxia
- Infants of diabetic mothers
- Intrauterine growth restriction

Late-Onset Hypocalcemia (First Week of Life)

- High phosphate load with or without hypoparathyroidism or vitamin D deficiency

Neonatal Hypoparathyroid Syndromes

- Parathyroid agenesis
- DiGeorge syndrome (22q11.2 deletions)
- Familial isolated hypoparathyroidism
- PTH* mutations

Autosomal Dominant Hypocalcemic Hypocalciuria

- Activating mutations of Ca^{2+} -sensing receptor

Neonatal Hypoparathyroidism Secondary to Maternal Hyperparathyroidism**Autoimmune Polyglandular Syndrome Type 1 (Autoimmune**

- Polyendocrinopathy–Candidiasis–Ectodermal Dystrophy)

Hypoparathyroidism Associated With Skeletal Dysplasias

- Kenny–Caffey syndrome
- Hypoparathyroidism–retardation–dysmorphism (Sanjad–Sakati) syndrome
- Osteogenesis imperfecta type II

Parathyroid Hormone Resistance (Transient Neonatal

- Pseudohypoparathyroidism)

Hypomagnesemia With or Without Distal Renal Tubular Acidosis

- Primary hypomagnesemia
- Renal tubular acidosis type 1

Abnormal Vitamin D (1,25-Dihydroxyvitamin D) Production or Action (“Hypocalcemic Rickets”)

- Vitamin D deficiency (secondary to maternal vitamin D deficiency)
- Acquired or inherited disorders of vitamin D metabolism
- Resistance to the actions of vitamin D

Hyperphosphatemia

- Excessive dietary phosphate
- Phosphate-containing enemas
- Rhabdomyolysis-induced acute renal failure
- Hyperphosphatemic renal insufficiency

“Hungry Bones Syndrome” (Mineralization Outpacing Osteoclastic Bone Resorption)**Other Causes**

- Metabolic or respiratory alkalosis
- Phototherapy
- Long-chain 3-hydroxyacyl-coenzyme A dehydrogenase deficiency
- Pancreatitis
- Sepsis, septic shock
- Rotavirus gastroenteritis
- Osteopetrosis and other skeletal dysplasias
- Pseudohypocalcemia (hypoalbuminemia)
- Medications
 - Bicarbonate
 - Rapid transfusion or plasmapheresis with citrated blood
 - Furosemide induced
 - Lipid infusions

“late” occurring hypocalcemia (Box 95.1) have different causes, usually occur in different clinical settings, and should prompt different approaches to evaluation and management.

Clinical Findings

Most infants with hypocalcemia are asymptomatic. Hypocalcemic signs in neonates are variable and may not correlate with the magnitude of the decline in calcium level. Calcium ions couple excitation and contraction in skeletal and cardiac muscle, so

increased neuromuscular excitability (tetany) is a cardinal feature of hypocalcemia. Such infants are jittery and hyperactive and frequently exhibit muscle jerks and twitches that are induced by environmental noise or other stimuli. Generalized or focal clonic seizures may occur. Other signs of neonatal tetany include poor feeding, hypotonia, apnea, tachycardia, tachypnea, high-pitched cry, and irritability (Thomas et al., 2012). Occasionally, respiratory or gastrointestinal rather than neurologic signs predominate. Rare presentations include inspiratory stridor caused by laryngospasm, wheezing caused by bronchospasm, or vomiting possibly resulting from pylorospasm, which may cause hematemesis or melena. At times the gastrointestinal signs are severe enough to mimic those of intestinal obstruction (Tohme and Bilezikian, 1993). Carpopedal spasm and Chvostek sign are not as reliably elicited in hypocalcemic newborns as in older children or adults. Hypocalcemia characteristically causes prolongation of the QT interval in the electrocardiogram (Benoit et al., 2005). Hypocalcemia prolongs phase 2 of the action potential and is associated with early afterrepolarizations and triggers dysrhythmias.

Early Neonatal Hypocalcemia

Hypocalcemia occurring during the first 3 days of life, usually between 24 and 48 hours postpartum, is termed *early neonatal hypocalcemia*. It is an exaggeration of the normal decline in circulating calcium concentration. Early neonatal hypocalcemia is typically encountered in any of four circumstances: prematurity, severe perinatal stress or asphyxia, maternal diabetes, or significant intrauterine growth restriction (IUGR).

In preterm infants there is a steeper and more rapid postnatal decline in serum calcium concentration. The magnitude of the depression is inversely proportional to gestational age. Approximately one-third of premature infants and most very low-birthweight (VLBW) infants have low total serum calcium level (<7.0 mg/dL) during the first 2 days after birth. However, the fall in Ca^{2+} concentration is not proportional to the fall in total calcium concentration, and the ratio of ionized to total calcium in these newborns is higher than at term. This “sparing” of Ca^{2+} may be related to the lower serum protein concentration and pH in prematurity. Multiple factors contribute to the fall in total serum calcium concentration, including low intake of milk, impaired response to PTH, and hypoalbuminemia, which does not lower the Ca^{2+} concentration. The sparing effect on Ca^{2+} concentration explains the frequent absence of hypocalcemic signs in preterm infants.

The neonatal parathyroid glands, regardless of the degree of prematurity, can mount an appropriate PTH response to hypocalcemia. Hypocalcemia in extremely preterm newborns (Rubin et al., 1991) or in infants undergoing cardiac bypass (Robertie et al., 1992) stimulates increases in serum PTH level at least as great as those seen in adults during citrate-induced hypocalcemia (Grant et al., 1990). PTH resistance plays an uncertain role in early neonatal hypocalcemia. A several-day delay in the phosphaturic and renal cAMP responses to PTH has inconsistently been reported, suggesting that there might be a maturational delay in renal responses to PTH. Calcitonin concentration usually peaks at 12 to 24 hours of life. The preterm infant’s exaggerated rise in calcitonin concentration may also promote hypocalcemia (Jain et al., 2010).

Early neonatal hypocalcemia with hyperphosphatemia is frequently observed in severely stressed or asphyxiated infants. Possible mechanisms include increased phosphate load caused by tissue catabolism, renal insufficiency, and acidosis. There is an exaggerated serum calcitonin response and elevated PTH levels. Low serum

Ca^{2+} and elevated serum magnesium levels have been correlated with the severity of hypoxic–ischemic encephalopathy and poor outcome (Ilves et al., 2000).

Hypocalcemia occurs in at least 10%–20% of infants of diabetic mothers (IDMs) (Rosenn et al., 1996). IDMs show an exaggerated postnatal drop in circulating calcium levels compared with gestational-age controls that typically occurs between 24 and 72 hours after birth and is often associated with hyperphosphatemia. The course is usually similar to that of early neonatal hypocalcemia in preterm infants, although hypocalcemia sometimes persists for several additional days. The greater bone mass and relative undermineralization typical of macrosomic IDMs may increase the neonatal demand for calcium, producing a deeper and prolonged decline in postnatal serum calcium levels. In addition, magnesium deficiency might play a significant role. Urinary magnesium losses occur with glycosuria, which may lead to significant maternal magnesium deficiency followed by fetal magnesium deficiency. Magnesium deficiency in these infants can lead to decreased PTH production and action (Banerjee et al., 2003; Rubin et al., 1991). Similar mechanisms may come into play in the transient hypocalcemia often observed in small-for-gestational-age infants. Hypercalcitonemia, hypoparathyroidism, abnormalities in vitamin D metabolism, and hyperphosphatemia have all been implicated, but none has been consistently found.

Neonatal hypocalcemia in IDMs has been associated with the severity and duration of maternal diabetes and inadequate glycemic control. Not surprisingly, preterm IDMs who have sustained IUGR and asphyxia as a result of uteroplacental insufficiency invariably become quite hypocalcemic. In recent years, improved metabolic control for pregnant diabetic women has markedly diminished the occurrence and severity of early neonatal hypocalcemia (Demarini et al., 1994). Healthy IDMs who are able to start milk feedings on the first day do not require serum calcium monitoring unless suspicious signs (e.g., jitteriness, stridor) are noted.

Hypocalcemia occurs with increased frequency in infants with IUGR. The mechanism is thought to involve decreased transfer of calcium across the placenta as a result of uteroplacental insufficiency.

Late Neonatal Hypocalcemia

Late neonatal hypocalcemia develops after 3 to 5 days of life and typically occurs at the end of the first week. It occurs more frequently in term than in preterm infants and is not usually associated with maternal diabetes, birth trauma, or asphyxia. Historically, late-onset hypocalcemia is associated with ingestion of cow's milk or formula with a high phosphate load (Institute of Medicine Standing Committee on the Scientific Evaluation of Dietary Reference Intakes, 1997). A previous review reported that excess phosphorus intake can disturb the absorption of calcium (Kim, 2007). The high phosphate level increases calcium deposition in bone and antagonizes PTH secretion and action, leading to hypocalcemia (Venkataraman et al., 1985). However, the widespread use of high-phosphorus formula in the United States and elsewhere contrasts with the rarity of this condition, which suggests that infants who develop phosphate-induced late neonatal hypocalcemia may have an otherwise undetected renal phosphate excretion problem.

The hyperphosphatemia may also result from various combinations of immature renal tubular phosphate excretion, transiently low levels of circulating PTH, hypomagnesemia, and inadequate maternal vitamin D intake. A relatively high dietary phosphate load coupled with a low GFR leads to an increase in serum phosphate levels and a reciprocal decline in serum calcium levels.

The physiologic response to hypocalcemia is an increase in PTH secretion, leading to increased urinary phosphate excretion and tubular calcium resorption. Serum calcium levels frequently increase when these infants are placed on a low-phosphate formula and supplemental calcium diet. After several days to weeks, serum PTH level usually increases, and the infants then can tolerate more dietary phosphate. The pathogenesis of this “transient hypoparathyroidism” in late neonatal hypocalcemia is not readily apparent. Some of these infants show a persistent or recurrent inability to mount an adequate PTH response to a hypocalcemic challenge, indicating partial hypoparathyroidism.

In other infants, maternal vitamin D deficiency can cause late (or occasionally “early”) neonatal hypocalcemia. This possibility is checked by measurement of maternal and neonatal serum 25(OH) D levels. Maternal vitamin D deficiency is implicated by the increased incidence of late neonatal hypocalcemia in winter due to inadequate sunlight exposure. The high prevalence of enamel hypoplasia of incisor teeth reported in affected infants indicates that the mineralization defect begins during the third trimester of pregnancy.

Hypocalcemia and hyperphosphatemia after the first 3 to 5 days always should prompt a thorough investigation for the underlying causes (Box 95.1). Hypocalcemia in this setting usually implies primary or secondary dysregulation of (1) the parathyroid–renal (PTH–1,25[OH]₂D) axis, (2) hypomagnesemia, or (3) renal insufficiency. The primary hormonal and end-organ disturbances that cause neonatal hypocalcemic syndromes are described later. As a cautionary note, observations of generally favorable neurologic outcomes in newborns with hypocalcemic or hypomagnesemic seizures may be valid for those who have a nutritional cause but are less relevant to patients with associated medical conditions. In this group, neurologic prognosis may be more closely related to the causative disorder (Lynch and Rust, 1994).

Hypocalcemia Caused by Hypoparathyroid Syndromes

The biochemical hallmarks of hypoparathyroidism are hypocalcemia and hyperphosphatemia in the presence of normal renal function. Serum PTH concentrations are inappropriately low or undetectable. Cytogenetic and molecular genetic diagnosis permits characterization of several types of congenital hypoparathyroidism. Isolated hypoparathyroidism is usually sporadic but may show X-linked, autosomal recessive, or autosomal dominant inheritance.

Congenital hypoparathyroidism is a common feature of DiGeorge syndrome (DGS). This disorder arises from a failure of migration of neural crest cells into the third and fourth pharyngeal pouches. Fully expressed DGS comprises hypoparathyroid hypocalcemia, thymic hypoplasia with defects in T-cell immunity, conotruncal cardiac defects, palatal insufficiency, dysmorphic facial features, and neurobehavioral and psychiatric features. DGS, velocardiofacial (Shprintzen) syndrome, and conotruncal face anomaly (Takao) syndrome commonly result from contiguous gene deletions in the same chromosomal region.

Most patients with a clinical diagnosis of DGS share a common 1.5- to 3-megabase deletion (monosomy or partial monosomy) of chromosome region 22q11.2, but there is molecular heterogeneity and rearrangement within this region (Shaikh et al., 2000). The size of the deletion does not correlate with the clinical phenotype. Haploinsufficiency of the TBX1 (T-box 1) transcription factor gene may be responsible for most features. Studies showed patients with point mutations in the gene encoding TBX1 manifested all major phenotypes of DGS (Yagi et al., 2003). Fluorescence in situ hybridization (FISH) using 22q11 probes had a higher detection

rate than high-resolution G-band karyotyping. However, the most sensitive (and preferred) laboratory assay is array-comparative genomic hybridization. Additionally, rarer identification of other cytogenetic abnormalities suggests that several distinct molecular defects (Rope et al., 2009) can lead to disturbed cranial neural crest cell migration and DGS phenotypes.

DiGeorge syndrome affects an estimated 1 in 4000 live births. It occurs sporadically or is transmitted as a variably penetrant autosomal dominant trait. Sporadic loss in the DGS chromosomal region is more common than parental transmission. In members of the same family, DGS may be associated with different phenotypic features. It often manifests itself in the first week of life with hypocalcemic tetany or seizures. Craniofacial features include microretrognathia, mandibular hypoplasia, submucous cleft palate, low-set and abnormal pinnae, telecanthus with short palpebral fissures, short philtrum, and a relatively small mouth. The presence of cardiac outflow tract or aortic arch abnormalities (especially pulmonary atresia/tetralogy of Fallot, type B interrupted aortic arch, truncus arteriosus, anomalies of aortic arch laterality, or abnormal branching of the brachiocephalic vessels) should prompt genetic investigation even in the absence of other DGS features. Parents of an infant with DGS should be screened for carrier status. These neonates require close anticipatory monitoring for the onset of hypocalcemia.

A normal serum PTH level obtained when an infant is relatively normocalcemic does not exclude the diagnosis of DGS. Absence of a thymic shadow on chest radiograph is not a reliable indicator. Infants with DGS may show resolution of hypoparathyroidism by early childhood, although PTH reserves may remain inadequate for defense against hypocalcemic stresses.

Hypoparathyroidism is a prominent feature of several rare skeletal dysplasias. Kenny–Caffey syndrome is a rare osteosclerotic bony dysplasia associated with hypocalcemia and ocular abnormalities (Tahseen et al., 1997). Autosomal recessive and autosomal dominant inheritance patterns have been described. Features include IUGR, transient neonatal hypoparathyroidism, short stature, macrocephaly, delayed fontanel closure, dysmorphic facies, and cortical thickening of tubular bones. The recessive form of Kenny–Caffey syndrome is the same disorder as hypoparathyroidism–retardation–dysmorphism (HRD) syndrome, which is also known as *Sanjad–Sakati syndrome*. HRD syndrome is an extremely rare disorder characterized by congenital hypoparathyroidism, growth retardation, characteristic facies (deep-set eyes, depressed nasal bridge, beaked nose, long philtrum, thin upper lip, large and floppy earlobes), small hands and feet, skeletal defects, and developmental delay (Sanjad et al., 1991). The loci for HRD syndrome and recessive Kenny–Caffey syndrome and HRD syndrome are allelic on chromosome band 1q42–q43. Parvari et al. (2002) have identified mutations in the gene encoding tubulin-specific chaperone E (*TBCE*) in both disorders. Hypoparathyroidism is also common in children with Kearns–Sayre syndrome (a mitochondrial myopathy associated with oculocraniosomatic disease) and Barakat syndrome (nerve deafness, refractory nephrosis, and renal failure). Knisely et al. (1988) showed that acute parathyroid hemorrhage (“parathyroid apoplexy”) is a common event in osteogenesis imperfecta type II and may contribute to early death.

The parathyroid glands are an infrequent target for autoimmunity, the exception being autoimmune polyglandular syndrome type 1 (APS 1), also known as *autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy* (Brown, 2009). APS 1 is a rare autosomal recessive disorder characterized by hypoparathyroidism, adrenal insufficiency, and chronic mucocutaneous candidiasis (Eisenbarth

and Gottlieb, 2004). It results from inheritance of mutations in an autoimmune regulator gene (*AIRE*). Candidiasis is usually the initial clinical manifestation, most often occurring in patients younger than 5 years. Hypoparathyroidism occurs next, usually in patients younger than 10 years. Hypoparathyroidism most often precedes development of hypoadrenocorticism. Affected individuals often eventually develop chronic hepatitis, malabsorption, juvenile-onset pernicious anemia, alopecia, and primary hypogonadism.

The association of several forms of autosomal dominant and autosomal recessive congenital hypoparathyroidism with allelic variants of the *preproPTH* and *CaSR* genes has advanced diagnosis and therapy for these disorders. Affected infants have subnormal or undetectable serum PTH levels but do not have congenital anomalies or developmental defects, DGS locus deletions, candidiasis or autoimmune polyglandular failure, or antiendocrine antibodies. Autosomal dominant and autosomal recessive forms of familial isolated hypoparathyroidism have been related to mutations in the *preproPTH* gene (Sunthornthevarakul et al., 1999). Activating mutations of *CaSR* can cause isolated hypoparathyroidism. Autosomal dominant hypocalcemia (ADH) is commonly caused by a gain-of-function mutation in the *CaSR* gene (Egbuna and Brown, 2008). The *CaSR* gene is located on chromosome band 3q13.3–q21, and it encodes a cell-surface protein that is expressed in the PTH-producing chief cells of the parathyroid glands and kidney tubules. Activation of the gene suppresses the secretion of PTH and renal calcium reabsorption from the cortical thick ascending limb (Lienhardt et al., 2001). The parathyroid and renal calcistat is reset downward, so hypocalcemia does not elicit normal compensatory PTH secretion or renal calcium reabsorption. Most patients with ADH are asymptomatic. Children, in particular, may become symptomatic with seizures and neuromuscular irritability during periods of stress such as febrile illness. Serum calcium level is usually in the range of 6 to 8 mg/dL (1.5 to 2.0 mmol/L), with normal or only slightly low serum PTH concentrations. Because de novo *CaSR* mutations producing *CaSR* hyperfunction are not uncommon (Egbuna and Brown, 2008), mutational analysis of the *CaSR* gene should be considered in the work-up of isolated hypoparathyroidism in infants, especially when hypocalcemia manifests itself with inappropriately normal urinary calcium excretion (relative hypercalciuria). Hypercalciuria and nephrocalcinosis can develop even when serum calcium concentration remains below the normal range. It is important to distinguish hypocalcemia due to an activating mutation of *CaSR* gene from isolated hypoparathyroidism because ADH patients can develop nephrocalcinosis and renal impairment during treatment with calcium and vitamin D. Therefore these patients require close monitoring of urinary calcium excretion for adjustment of therapy with 1,25(OH)₂D analogues.

Pseudohypoparathyroidism refers to a heterogeneous group of disorders that are usually inherited as an autosomal dominant trait characterized by hypocalcemia, hyperphosphatemia, and increased serum PTH concentrations due to PTH hormone resistance of peripheral tissues. Deletion of the PTH/PTHrP receptor is embryologically or perinatally lethal. Loss of one allele for *GNAS1*, which encodes G_sα, the G protein α subunit required for receptor-stimulated cAMP generation, produces pseudohypoparathyroidism type 1A (PHP1A) (Levine, 2012). In patients with PHP1A, there is the characteristic phenotype of Albright hereditary osteodystrophy (short stature, obesity, round face, brachymetacarpalism, and subcutaneous calcifications), and it is associated with multihormone resistance (e.g., thyroid-stimulating hormone, gonadotropins and

growth hormone). Isolated PTH resistance in the absence of a somatic phenotype is called *pseudohypoparathyroidism type 1B*. This disorder is an imprinting defect in which both *GNAS1* alleles have an unmethylated (paternal) pattern (Liu et al., 2000). Although most patients who eventually receive a diagnosis of PTH resistance syndrome are usually not hypocalcemic during the first month of life, transient neonatal pseudohypoparathyroidism has occasionally been reported (Minagawa et al., 1995). Individuals with pseudopseudohypoparathyroidism have the clinical phenotype of Albright hereditary osteodystrophy (AHO) but normal serum calcium, phosphorus, and PTH levels. Pseudohypoparathyroidism type 2 is characterized by hypocalcemia, hyperphosphatemia, and increased serum PTH level. However, individuals usually lack physical features associated with AHO (Mantovani, 2011).

Neonatal Hypocalcemia Associated With Maternal Hyperparathyroidism

Hypocalcemia is commonly observed in newborns of hyperparathyroid mothers (Cakir et al., 2013). These newborns may show increased neuromuscular irritability during the first 3 weeks of life but, occasionally, do so much later as limited PTH reserve and latent hypoparathyroidism emerge under stress or with time. The serum calcium levels usually range from 5.0 to 7.5 mg/dL, and the serum phosphate levels are often greater than 8.0 mg/dL. Hypocalcemic signs may be exacerbated by high-phosphate diets or maternal vitamin D deficiency. In some instances, signs of hypocalcemia can be quite severe and may be resistant to several weeks of calcium replacement therapy.

In maternal hyperparathyroidism the increased maternal serum calcium concentration facilitates transplacental calcium transport, producing fetal hypercalcemia greater than the moderate elevations of serum calcium concentration normally observed in the third trimester. As a result, fetal PTH secretion is suppressed (Jacobsen et al., 1978). The suppressed parathyroids are unable to maintain normal serum calcium levels postpartum. The reason for the hypomagnesemia observed in some infants born to hyperparathyroid mothers is uncertain, but this derangement may be due to (1) maternal magnesium depletion as a complication of hyperparathyroidism, (2) transient neonatal hypoparathyroidism, or (3) hyperphosphatemia, which may result from transient hypoparathyroidism or high dietary phosphate intake, or both.

Maternal serum calcium and phosphorus levels should be assayed whenever this diagnosis is suspected. Hypocalcemic tetany occurring in the infant may lead to a diagnosis of hyperparathyroidism in an asymptomatic mother. Maternal serum calcium levels in the upper normal range may be falsely reassuring if the samples were obtained during pregnancy, a time when serum calcium levels normally decline.

Neonatal Hypocalcemia Associated With Hypomagnesemia or Renal Tubular Acidosis

Hypomagnesemia causes hypocalcemia by interfering with the parathyroid cell CaSR-mediated release of PTH and by blunting end-organ PTH response. Hypomagnesemia with secondary hypocalcemia (HOMG1), can present in the first weeks of life as persistent hypocalcemia, tetany, and seizures uncontrolled by anticonvulsants or calcium therapy. Delay in establishing the diagnosis may lead to permanent neurologic impairment. This rare autosomal recessive disorder results from defective intestinal magnesium absorption and renal magnesium leak. Hypocalcemia is a secondary consequence of parathyroid failure and PTH resistance

as a result of severe magnesium deficiency. HOMG1 is caused by mutations in the *TRPM6* gene, a member of the transient receptor potential channel gene family expressed in intestinal epithelia and renal tubules (Schlingmann et al., 2005). Treatment includes immediate administration of magnesium, usually intravenously, followed by high-dose oral magnesium.

Several forms of primary renal hypomagnesemia have been described, including autosomal recessive familial hypomagnesemia with hypercalciuria and nephrocalcinosis caused by mutations in the claudin 16 (paracellin 1) gene (Simon et al., 1999) and a genetically heterogeneous autosomal dominant “isolated renal magnesium wasting.” The initial symptoms may include recurrent urinary tract infections, polyuria and polydipsia, moderate metabolic acidosis with an inappropriately high urine pH, muscle weakness, persistent tetany, failure to thrive, sensorineural hearing loss, and distal tubular acidosis. All patients exhibit hypercalciuria and nephrocalcinosis, and 50% of cases usually require renal replacement therapy in the second decade of life. The distal acidification defect is probably secondary to a medullary interstitial nephropathy. The serum magnesium level is frequently less than 0.8 mg/dL (normal range 1.6 to 2.8 mg/dL). High-dose enteral magnesium administration leads to increases in serum PTH and calcium levels and renal phosphate clearance. Kidney transplant normalizes serum magnesium and urinary calcium.

A transient hypomagnesemia in newborns often occurs in association with hypocalcemia. Less commonly, the serum calcium level may be normal. In transient hypomagnesemia the decrease in serum magnesium level typically is less severe (0.8 to 1.4 mg/dL) than in magnesium transport defects. In many infants with transient hypomagnesemia, the serum magnesium level increases spontaneously as the serum calcium level normalizes following the administration of calcium supplements. However, in other cases, hypocalcemia responds poorly to calcium therapy, but when magnesium salts are given, serum calcium and magnesium levels both rise.

Secondary hypomagnesemia from renal magnesium wasting can result from drug administration (e.g., loop diuretics, aminoglycosides, amphotericin B) or from urinary tract obstruction. It also may occur during the diuretic phase of acute renal failure. This disorder may be mistaken for neonatal hypoparathyroidism because of tetany and hypocalcemia or Bartter syndrome (hypokalemic alkalosis with hypercalciuria) because of secondary potassium wasting. An index of suspicion should be raised whenever hypomagnesemia occurs in one of these situations. The finding of low serum magnesium levels with inappropriately high urinary magnesium excretion confirms a diagnosis of renal magnesium wasting. Hypokalemia is a common laboratory feature of magnesium depletion. Attempts to replace the potassium deficit with potassium alone are usually unsuccessful unless magnesium is given concurrently.

Distal renal tubular acidosis (RTA1) is characterized by hypocalcemia, hypercalciuria, various degrees of hypomagnesemia, hyperchloremia, low serum bicarbonate level, and a fixed urinary specific gravity and urinary pH (about 5.0). The mineral excretion defect leads to nephrocalcinosis and metabolic bone disease. RTA1 sometimes manifests itself during early infancy, when hypocalcemia may precede the renal tubular acidosis.

Hypocalcemia Resulting From Vitamin D Disorders

Vitamin D increases the intestinal absorption of calcium. In older children and adults, disorders of vitamin D intake or metabolism rarely present as isolated hypocalcemia. Instead, most patients with

abnormalities in either production or action of $1,25(\text{OH})_2\text{D}$ have rickets or osteomalacia. In sharp contrast, young infants may exhibit hypocalcemic tetany before rachitic features become conspicuous. Abnormalities in vitamin D metabolism can be divided into three broad categories: vitamin D deficiency, acquired or inherited disorders of vitamin D metabolism, and resistance to vitamin D actions.

Maternal vitamin D deficiency is the major risk factor for neonatal vitamin D deficiency manifesting itself as hypocalcemia. Maternal vitamin D deficiency is becoming less common in countries where dairy products and other foods are supplemented with vitamin D. It is still a common and serious health problem of women of reproductive age and their infants in developing countries. Female immigrants from the Middle East or South Asia who wear traditional concealing dress, have inadequate dietary vitamin D intake, or are dark skinned are at particularly high risk (Dijkstra et al., 2007; Hobbs et al., 2009), especially during pregnancy. Breastfed infants of lactovegetarian mothers are also susceptible to early-onset hypocalcemic rickets. Nutritional rickets in newborns can be prevented by daily supplementation of 400 international units (IU) for infants and 400 IU daily for mothers during pregnancy and lactation or 1000 IU daily if supplementation is begun in the third trimester.

Intestinal absorption of fat-soluble vitamin D requires a functioning exocrine pancreas, biliary tract, and bowel mucosa. Consequently, pregnant women with malabsorption syndromes may be vitamin D deficient.

Anticonvulsant therapy (e.g., with phenobarbital or diphenylhydantoin) during pregnancy, which increases hepatic catabolism of $25(\text{OH})\text{D}$, can also induce maternal and fetal vitamin D deficiency. Pregnant women who take anticonvulsants should receive vitamin D supplementation (800 to 1000 IU per day).

Phosphate-Induced Hypocalcemia

Phosphate directly precipitates calcium in bone or soft tissues by inhibiting bone resorption and blocking renal synthesis of $1,25(\text{OH})_2\text{D}$. Conditions leading to phosphate-induced neonatal hypocalcemia include excessive phosphate intake, rhabdomyolysis-induced acute renal failure, and hyperphosphatemic renal insufficiency. Phosphate-containing enemas can produce significant phosphate absorption (Marraffa et al., 2004). Their use is hazardous and contraindicated for infants. Chronic renal failure is the primary cause of secondary hyperparathyroidism. Patients with mineral metabolism disorders commonly have low serum calcium levels, hyperphosphatemia, and calcitriol deficiency. In uremic conditions, however, the parathyroid glands become hyperplastic. In recent years fibroblast growth factor 23 (FGF-23) has been identified (Cozzolino et al., 2009). FGF23 is a bone-derived hormone that regulates systemic phosphate hemostasis and vitamin D metabolism. FGF23 inhibits renal tubular reabsorption of phosphate independently of PTH (Quarles, 2012).

Other Causes of Neonatal Hypocalcemia

It is important to recognize that hypocalcemia may occur whenever skeletal mineralization significantly outpaces the rate of osteoclastic bone resorption. Examples of this type of hypocalcemia occur with overzealous vitamin D replacement in infants with rickets or hypoparathyroidism (Thacher et al., 2006). Pancreatitis can cause hypocalcemia and tetany through the action of pancreatic lipase on retroperitoneal and omental fat to release free fatty acids (FFAs). FFAs avidly chelate calcium and remove it from the ECF. Pancreatitis may also result in release of pancreatic calcium-lowering factors

(Tomomura et al., 1995). Hypocalcemia is commonly seen in critically ill patients with sepsis. It is believed to be due to parathyroid gland suppression, failure to activate vitamin D, and calcium chelation (Kelly and Levine, 2013). Neonatal or infantile hypocalcemia and hypocalcemic seizures may accompany long-chain 3-hydroxyacyl-coenzyme A dehydrogenase deficiency and severe cases of rotavirus gastroenteritis (Foldenauer et al., 1998). Hypocalcemic jitteriness or seizures can be the presenting sign of infantile osteopetrosis (Chen et al., 2003). It is thought to arise from the failure of osteoclasts to resorb immature bone. Prompt recognition permits early referral for bone marrow or hematopoietic stem cell transplant.

Several common therapeutic interventions can induce hypocalcemia. Bicarbonate therapy, as well as any form of metabolic or respiratory alkalization, decrease both Ca^{2+} levels and bone turnover. Rapid blood transfusion or plasmapheresis can promote calcium complexes with the infused citrate, decreasing Ca^{2+} levels. Hypocalcemia after initiation of ECMO is related to the composition of the circuit-priming solution and to acute citrate loading and may lead to hemodynamic instability (Meliones et al., 1995). Large doses of ethylenediaminetetraacetic acid-containing contrast dyes have also been reported to cause hypocalcemia (Brown et al., 2006). Furosemide therapy, a therapy for hypercalcemia, promotes calciuresis and nephrolithiasis. Phototherapy for hyperbilirubinemia may be associated with mild hypocalcemia. This effect has been attributed to decreased melatonin secretion, which potentiates glucocorticoid actions on bone metabolism. Lipid infusions may elevate serum levels of FFAs, which form insoluble complexes with calcium. Most of these effects are transient, and cessation of therapy is followed by a return to normal serum calcium levels. The major exception is aggressive furosemide therapy, which, when prolonged, may lead to bone demineralization and renal dysfunction.

Treatment

The decision to treat hypocalcemia in an infant depends on the severity of the hypocalcemia and the presence of clinical signs and symptoms. The morbidity associated with calcium treatment must be weighed against the potential benefits. Hypocalcemic preterm infants who have no symptoms and are not ill from any other cause probably do not need specific treatment. Early neonatal hypocalcemia should resolve by day 3. Some clinicians begin treatment in preterm newborns once serum calcium levels have dropped to 6.0 to 6.5 mg/dL or after Ca^{2+} concentration has decreased to 2.5 to 3.0 mg/dL. Some advocate initiation of prophylactic calcium infusions (or calcium-containing parenteral nutrition) for all extremely low-birthweight infants (ELBW) within the first 24 hours. There is no role for prophylaxis or treatment with pharmacologic doses of vitamin D. For newborns who exhibit cardiovascular compromise (e.g., severe respiratory distress, pulmonary hypertension, asphyxia, sepsis) or who require cardiotoxic drugs or blood pressure support, monitoring of blood Ca^{2+} concentration is particularly helpful, with the aim of preventing the onset of significant hypocalcemia.

The mainstay of treatment for neonatal hypocalcemia is intravenous (IV) administration of calcium salts. Calcium gluconate is preferred over calcium chloride (which, in sufficient doses, produces hyperchloremic acidosis) or calcium lactate. A 10% solution of calcium gluconate contains 9.4 mg elemental calcium per mL. A constant infusion of approximately 45 to 75 mg/kg per day of elemental calcium usually produces a sustained increase in serum calcium level (7 to 8 mg/dL). Bolus infusions are hazardous and only transiently effective.

The risks associated with calcium infusions are minimized by attention to detail. Rapid IV infusion of calcium can cause a sudden elevation in serum calcium level, leading to bradyarrhythmias. Bolus infusion of calcium should be reserved for treatment of hypocalcemic tetany and seizures. Extravasation of calcium solutions into subcutaneous tissues may cause necrosis and subcutaneous calcification. Therefore meticulous care of peripheral IV catheter sites is particularly important when calcium-containing solutions are infused. Inadvertent intrahepatic infusion of calcium through an umbilical vein catheter (due to failure to reach the inferior vena cava) can cause hepatic necrosis. Rapid intraaortic infusion via an umbilical artery can cause arterial spasm and, at least experimentally, intestinal necrosis.

Hypocalcemic Crisis. Acute hypocalcemia constitutes an emergency that requires prompt attention. For emergency treatment of a hypocalcemic crisis with seizures or tetany, 1 to 2 mL/kg (100 to 200 mg/kg calcium gluconate) of a 10% solution of calcium gluconate should be given within 5 to 10 minutes. The dose can be repeated in 10 minutes if no response occurs. Calcium should not be administered rapidly intravenously because hypercalcemia may adversely affect cardiac conduction; monitoring of the electrocardiogram QT interval is useful in guiding therapy. Alternatively, calcium chloride (0.2 mL/kg) can be given. If necessary, IV calcium therapy may be repeated three or four times in 24 hours to help control acute symptoms. After short-term treatment, maintenance calcium gluconate should be added to IV fluid. Careful observation of the infant and infusion site is essential, and the infusion should be discontinued if there is bradycardia or when the desired clinical result is obtained. Serum calcium must be frequently monitored during infusion, and calcium should not be mixed with fluids containing phosphate or bicarbonate to avoid precipitation (Zhou and Markowitz, 2009).

Nonemergency Treatment. After acute symptoms have been controlled, calcium therapy should be continued as needed to maintain a serum calcium concentration above 7.0 mg/dL. In part, the level of serum calcium to be achieved depends on serum total protein, particularly albumin. In hypoalbuminemic infants, lower levels of total serum calcium are normally present. The dose varies with age. In preterm and sick infants for whom oral intake is limited, 5 to 8 mL/kg of 10% calcium gluconate (45 to 75 mg/kg elemental calcium) may be infused with IV fluids in a 24-hour period. For older infants and children, a starting dose of 200 mg/kg calcium gluconate (20 mg/kg elemental calcium) each 24 hours should be provided. The lower dose range is preferred whenever there is hyperphosphatemia. If oral feedings are tolerated, 10% calcium gluconate may be given in the 50- to 150-mg/kg per day range of elemental calcium in four to six divided doses. Alternatively, calcium glubionate (Neo-Calglucon), which contains 23.6 mg elemental calcium per mL, may be given in a dosage of 2 mL/kg per day divided into feedings. Orally administered calcium gluconate is better tolerated by young infants because the high sugar content and osmolality of calcium glubionate may cause gastrointestinal irritation or diarrhea. IV or oral calcium supplements should be continued until the serum calcium level stabilizes.

Dietary factors and hypoparathyroidism are important in the pathogenesis of late neonatal hypocalcemia. Therefore therapy is often directed at reducing the phosphate load and increasing the calcium-to-phosphorus ratio of feedings to 4:1. This can be accomplished by the use of low-phosphorus feedings such as human milk or Similac PM 60/40 (Abbott Nutrition) in conjunction with calcium supplements. These interventions inhibit intestinal

absorption of phosphorus. Phosphate binders are not generally necessary. Serum calcium and phosphorus levels should be monitored at least once to twice weekly, and the use of calcium supplements should be discontinued in a stepwise fashion after several weeks.

Magnesium Administration. When hypomagnesemia contributes to hypocalcemia, administration of magnesium salts is indicated. Magnesium may be given intramuscularly as a 50% solution of magnesium sulfate (50% $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ contains 4 mEq/mL magnesium). The suggested intramuscular or IV dose of 50% magnesium sulfate is 0.1 to 0.2 mL/kg. IV infusions should be administered slowly with use of electrocardiographic monitoring to detect rhythm disturbances, which may include prolonged atrioventricular conduction time and sinoatrial or atrioventricular block. The magnesium dose may be repeated every 12 to 24 hours, depending on the clinical and serum magnesium response. Many infants with transient hypomagnesemia will respond sufficiently to one or two magnesium injections. Infants with primary hypomagnesemia have permanent magnesium wasting. The low serum magnesium levels may require lifelong treatment with magnesium supplements.

Vitamin D Treatment. Infants with normal intestinal absorption who develop late hypocalcemia with vitamin D–deficiency rickets usually respond within 4 weeks to 1000 to 2000 IU/day oral vitamin D. These infants should receive at least 40 mg/kg per day of elemental calcium to prevent hypocalcemia because the unmineralized osteoid may avidly incorporate calcium once vitamin D is provided (“hungry bones” syndrome). PTH-dependent renal production of $1,25(\text{OH})_2\text{D}$ is deficient in all hypoparathyroid states, renal failure, or vitamin D–dependent rickets. Vitamin D metabolites that do not require renal 1α -hydroxylation should be administered. Calcitriol ($1,25[\text{OH}]_2\text{D}$) is indicated, usually starting with 0.25–1 $\mu\text{g}/\text{d}$ in two divided doses. The dose may be adjusted at 2- to 4-week intervals. Most patients with hypoparathyroidism require lifelong calcium and vitamin D supplementation. The goals of therapy are to relieve symptoms and maintain the serum calcium level in the low normal range (e.g., 8.0 to 8.5 mg/dL [2.0 to 2.1 mmol/L]) to prevent hypercalciuria and nephrocalcinosis (Bilezikian et al., 2011). Assessment of urinary calcium excretion by urinary calcium-to-creatinine ratio should be performed within 2 weeks of initiation of therapy. The urinary calcium measurement reflects the effect of therapy and monitors the risk of nephrocalcinosis. The ratio of 0.2 mg/mg or greater usually defines hypercalciuria in older children, but the age-dependent 95th percentile can be as high as 0.7 mg/mg for infants (Singh et al., 2003; Habbig et al., 2011). Periodic renal sonograms are also recommended to detect nephrocalcinosis.

It is essential that patients with hypocalcemia be aware that their calcium level should be monitored more frequently during intercurrent illnesses that may affect calcium absorption to prevent the development of hypocalcemia or severe hypercalcemia.

Recombinant Parathyroid Hormone Analogue. Studies have suggested subcutaneous injection of recombinant PTH can be an alternative therapy for hypoparathyroidism. However, such treatment poses a number of challenges, particularly fluctuations in calcium level. Further studies are needed to assess the long-term effects (Rejnmark et al., 2015).

Neonatal Hypercalcemia

Hypercalcemia is usually defined as total serum calcium concentration greater than 11.0 mg/dL and Ca^{2+} concentration greater than 5.0 mg/dL. Hypercalcemia in neonates may be asymptomatic if there are only mild elevations in calcium levels, but as calcium

levels start to rise above 12.0 mg/dL, then symptoms may start to manifest themselves. These may include poor weight gain, poor feeding, weakness, constipation, and polyuria. As calcium levels get higher (>14 mg/dL), more severe symptoms may present, such as vomiting, respiratory distress, apnea, hypotonia, lethargy, and seizures. The polyuria seen in hypercalcemic states is due to impairment in the kidney's concentration ability, leading to a state of nephrogenic diabetes insipidus (Berl, 1987). This may be partly due to inhibition of sodium chloride reabsorption in the loop of Henle, which impairs the osmotic gradient needed for concentration, as well as decreased antidiuretic hormone-mediated water permeability in the collecting tubules (Hebert, 1996). Usually there are no physical examination findings associated with hypercalcemia unless findings are associated with genetic syndrome dysmorphisms or subcutaneous fat necrosis. Hypertension can be seen, most likely due to the effects of hypercalcemia on vasoconstriction as well as possible effects on catecholamine (Eiam-Ong et al., 2004). Shortened QT interval may also be seen on electrocardiogram (Ahmed and Hashiba, 1988). When hypercalcemia is chronic, calcifications can be seen in multiple tissues and organs, including kidney, skin, subcutaneous tissue, heart (valves, arteries, muscle), lung, brain, and gastric mucosa. Nephrocalcinosis, nephrolithiasis, and osteitis fibrosa cystica (loss of bone mass and replacement with fibrous tissue with formation of cystic lesions due to increased osteoclastic resorption) may also be seen in chronic, untreated hypercalcemia. In infants the most clinically apparent manifestation of chronic hypercalcemia is poor growth and failure to thrive.

Neonatal hypercalcemia is associated with several clinical entities (Box 95.2). Normally calcium concentrations are tightly regulated by interplays between PTH, CaSR, calcitonin, and vitamin D analytes affecting intestinal and renal absorption of calcium.

• BOX 95.2 Causes of Neonatal Hypercalcemia

Hyperparathyroidism

CaSR mutations

- Neonatal severe hyperparathyroidism
- Familial hypocalciuric hypercalcemia

Maternal hypocalcemia

Mucopolidosis type II

Iatrogenic

- Hypophosphatemia
- Vitamin D intoxication
- Calcium supplement excess
- Hypervitaminosis A
- Extracorporeal life support

Hypercalcemia Associated With Skeletal Dysplasias

- Infantile hypophosphatasia
- Jansen metaphyseal chondrodysplasia (activating mutations of parathyroid hormone/parathyroid hormone-related protein receptor)

Other Causes

- Williams syndrome
- Idiopathic infantile hypercalcemia/25-hydroxyvitamin D 24-hydroxylase deficiency
- Subcutaneous fat necrosis
- Blue diaper syndrome
- Tumor-associated hypercalcemia (parathyroid hormone-related protein secretion)
- Congenital lactase deficiency
- Congenital sucrase-isomaltase deficiency
- Immobilization

Hypercalcemia may occur when there is a disruption in this system and can be due to multiple causes, which can be categorized on the basis of abnormalities of PTH, CaSR, intake, or other causes.

Neonatal Hyperparathyroid Syndromes Associated With CaSR Mutations

Inactivating mutations of CaSR can lead to a spectrum of hypercalcemic diseases that may range from severe presentations such as neonatal severe hyperparathyroidism (NSHPT) to mild presentations as seen in FHH. These mutations cause a shift in the dose-response curve for calcium to the right, so there is a higher setpoint for the CaSR, leading to higher serum calcium levels and an elevated or inappropriately normal PTH level. Urinary calcium-to-creatinine clearance ratios will be less than 0.01, and there will often be a family history of hypercalcemia although de novo mutations can be present. FHH is usually due to a heterozygous mutation, while NSHPT is due to a homozygous mutation; however, there have been cases of mild homozygous mutations leading to an FHH presentation and severe heterozygous mutation presenting more like NSHPT (Iacobone et al., 2015; Mayr et al., 2016).

FHH is an autosomal dominant disorder characterized by mild hypercalcemia, low renal excretion of calcium leading to hypocalciuria, and normal or mildly elevated PTH level. Usually FHH is asymptomatic with normal phosphorus, magnesium, and vitamin D levels and bone density. Presentation can be masked if there is concomitant vitamin D deficiency (Szcawinska et al., 2014). There are three types of FHHs. FHH type 1 is the most common form and accounts for 65% of cases. It is due to a loss-of-function mutation of the *CaSR* gene on chromosome band 3q21.1. FHH type 2 and FHH type 3 account for the rest of the cases and are due to a loss-of-function mutation of *GNA11* on chromosome band 19p13.3 or *AP2S1* on chromosome band 19q13.2-q13.3, respectively (Iacobone et al., 2015). *AP2S1* encodes adaptor-related protein complex 2, which is involved in endocytosis of CaSR. *GNA11* encodes G protein subunit α_{11} , which is involved in CaSR signaling (Vargas-Poussou et al., 2016). FHH type 3 may have a more severe presentation with higher calcium levels. FHH generally does not require treatment unless there is evidence of symptoms or complications due to hypercalcemia. Parathyroid glands can be normal or hyperplastic, and surgical resection is usually not helpful (Iacobone et al., 2015). Individuals with FHH may have children with NSHPT.

NSHPT is a rare, life-threatening disorder associated with elevated PTH level, elevated serum calcium level, elevated magnesium level, and low urinary excretion of calcium. It is diagnosed within the first 6 months of life, but severe forms will present as a critically ill newborn with symptoms of poor feeding, dehydration, lethargy, and respiratory distress. Elevated PTH level may lead to bony changes, including demineralization, fractures, and rickets. Homozygous mutations of *CASR* usually lead to a more severe presentation, and both parents have FHH. Heterozygous mutations of the gene may result in lower calcium levels and may be inherited from one parent or occur from a de novo mutation (Hendy and Cole, 2013; Mayr et al., 2016). Typically, these patients have large, hyperplastic parathyroid glands that need to be surgically removed. However, before surgery, hypercalcemia needs to be medically managed. This includes the use of sodium-containing fluids and diuretics to induce sodium diuresis and therefore urine calcium excretion. Medications such as bisphosphonates and calcimimetics can decrease serum calcium concentration as well. Pamidronate at 0.5 to 1 mg/kg and cinacalcet at 0.4 to 2 mg/kg per day have been used successfully in reported cases to decrease serum calcium

levels as patients await total parathyroidectomy (Iacobone et al., 2015; Mayr et al., 2016).

Neonatal Hyperparathyroidism Not Associated With *CASR* mutations

Other forms of inherited hyperparathyroidism include those seen in syndromes such as multiple endocrine neoplasia (MEN) 1, MEN 2A, and hyperparathyroidism–jaw tumor syndrome, but these conditions would present with hyperparathyroidism later in life. Secondary neonatal hyperparathyroidism may also be seen as a consequence of maternal calcium–PTH abnormalities. Maternal hypocalcemia during pregnancy will lead to decreased placental transport of calcium, fetal hypocalcemia, and subsequent hyperplasia of the parathyroid glands. This condition is transient and normally resolves within the first few weeks of life. Hypercalcemia and hypophosphatemia are not seen universally in these cases but bony changes secondary to elevated PTH level are common (Loughhead et al., 1990). Another condition that may lead to secondary hyperparathyroidism is mucopolidosis type II. Such cases present with elevated PTH level, normal calcium level, and bony changes and resolve with vitamin D and calcium supplementation. The cause is hypothesized to be secondary to diminished transplacental calcium transport as this condition is associated with abnormalities of the placenta (Unger et al., 2005).

Jansen metaphyseal chondrodysplasia is a syndrome that has features of hyperparathyroidism but low levels of PTH. In this condition, mutations of *PTHr1* lead to constitutive, ligand-independent activation of the receptor, causing hypercalcemia despite low serum PTH levels. Such patients will also have irregularities of the metaphysis and rachitic changes seen on x-ray. Other distinguishing features include short-limbed dwarfism with postnatal growth failure, hypertelorism, and mandibular hypoplasia (Schipani et al., 1996; Hsu and Levine, 2004).

Williams Syndrome and Idiopathic Infantile Hypercalcemia

Williams syndrome (WS) (or Williams–Beuren syndrome) is a genetic disorder due to the deletion of the Williams–Beuren syndrome critical region (WBSCR) of chromosome band 7q11.23, which includes the elastin gene (*ELN*). The deletion can be detected by FISH or deletion/duplication testing. It is usually due to a de novo mutation but can be transmitted in an autosomal dominant fashion. It is characterized by distinctive facial features (broad forehead, stellate iris, short nose, broad nasal tip, malar flattening, long philtrum, wide mouth, small jaw, large earlobes), mild intellectual disability, a social personality, short stature, cardiovascular disease (elastin arteriopathy, peripheral pulmonary stenosis, supravalvular aortic stenosis, hypertension), hypotonia, joint hyperextensibility, and endocrine abnormalities (hypercalcemia, hypothyroidism, early puberty). In infancy, inguinal or umbilical hernias, hypotonia, poor feeding, failure to thrive, developmental delays, and rectal prolapse may also be present (Morris, 1999).

About 30% of patients have hypercalciuria and 15% have idiopathic hypercalcemia. The hypercalcemia is noted during infancy and typically resolves by 2 to 4 years of life, although rarely it can persist into adulthood. The cause of the hypercalcemia is not well understood. PTH level is normal or low, and there is no consistent pattern in vitamin D metabolism to explain the abnormality. Hypercalciuria is relatively common, and nephrocalcinosis has been reported (Pober et al., 1993). Therefore early screening for hypercalcemia and hypercalciuria is warranted in infancy. The severity of the calcium abnormalities can range from mild to severe. Treatment consists of limiting calcium and vitamin D intake until

the condition resolves. More severe cases have also been treated with short courses of calcitonin, glucocorticoids, and pamidronate (Morris, 1999; Cagle et al., 2004).

A similar calcium profile as seen in WS has been described in certain infants classified as having idiopathic infantile hypercalcemia (IIH). These infants may have failure to thrive, dehydration, and nephrocalcinosis. They do not have all the same clinical features or gene deletion as WS and can be differentiated from WS through genetic testing. In IIH, hypercalcemia also resolves in the first few years of life, and treatment is similar to that of children with WS (Martin et al., 1984). The cause of the hypercalcemia used to be a mystery; however, recently mutations of *CYP24A1*, which encodes the enzyme 25(OH)D 24-hydroxylase have been implicated as a factor in IIH. This enzyme plays an important role in the metabolism and deactivation of 1,25(OH)₂D. Therefore a loss-of-function mutation in this gene leads to elevated 1,25(OH)₂D levels as well as exaggerated increases of these levels and subsequent hypercalcemia if vitamin D supplementation is given. Biochemically, this leads to hypercalcemia, hypercalciuria, suppressed PTH levels, increased intestinal calcium absorption, and elevated 1,25(OH)₂D levels. An elevated 25(OH)D to 24,25(OH)₂D ratio can also be seen (Schlingmann et al., 2011; Cools et al., 2015). Treatment involves limitation of vitamin D and calcium intake.

Neonatal Hypercalcemia Associated With Subcutaneous Fat Necrosis

Subcutaneous fat necrosis (SFN) is a panniculitis that develops in term or postterm infants. The lesions are erythematous to violaceous, indurated subcutaneous nodules and plaques that appear in the first few days of life (mean 4 days) and are typically found on the back, head, and arms. The lesions may initially be painful and resolve within the first few months of life. Biopsy of the nodules shows granulomatous necrosis in the subcutis with crystal-like structures in adipocytes and giant cells. The risk factors for the development of SFN include birth trauma, asphyxia, meconium aspiration, infections, and cutaneous trauma. Maternal risk factors may include gestational diabetes, preeclampsia, cocaine or calcium blocker use during pregnancy, and high risk of thrombosis (Mahe et al., 2007). SFN has also been recognized as a complication of therapeutic hypothermia for neuroprotection after hypoxic–ischemic encephalopathy that may occur days to weeks after treatment, with lesions occurring in areas in contact with the cooling blanket (Scheans, 2012).

Complications of SFN include mild to severe hypercalcemia, dyslipidemia, hypoglycemia, thrombocytopenia, and eosinophilia. Hypercalcemia may occur 1 to 2 months after delivery; therefore in infants with SFN calcium levels should be monitored regularly. Some of the hypercalcemia may be asymptomatic despite high levels of calcium (Mahe et al., 2007; Shumer et al., 2014). Hypercalciuria is often present, and nephrocalcinosis may occur that can persist into early childhood but does not seem to result in adverse renal outcomes (Shumer et al., 2014). The cause of the hypercalcemia is thought to be due to the uncontrolled production of 1,25(OH)₂D by activated macrophages that infiltrate the necrotic fat. This leads to increased intestinal absorption of calcium in the gut. The necrotic fat also releases calcium and prostaglandin E (increases bone turnover), which may exacerbate the hypercalcemia (Hsu and Levine, 2004; Shumer et al., 2014). Treatment includes hydration, furosemide therapy, and a low-calcium/low–vitamin D diet. However, SFN is also highly responsive to glucocorticoids. Severe, refractory cases have also been treated with bisphosphonates (Shumer et al., 2014).

Hypercalcemia Due to Iatrogenic Causes

Neonatal hypercalcemia may also be due to increased intake of calcium or vitamin D or decreased intake of phosphorus. Hypercalcemia because of phosphate depletion is most often seen in VLBW infants who are fed unsupplemented human milk that is low in phosphorus or given parenteral nutrition with inadequate phosphate. There is a high consumption of phosphorus by cells in growing newborns. If inadequate phosphorus is given, then phosphorus will be released through bone resorption, which in turn also releases calcium. This may also be associated with high alkaline phosphatase (ALP) levels. Low phosphorus levels will also stimulate increased renal production of $1,25(\text{OH})_2\text{D}$ and increased absorption of calcium through the gut (Warner et al., 1998; Guellec et al., 2015). The condition is preventable by anticipatory monitoring of serum calcium and phosphorus levels in high-risk infants.

Excessive supplementation with vitamin D may cause neonatal hypercalcemia. The excess vitamin D may be from improperly made formula, ingestion of cow's milk fortified with vitamin D, or overdose of vitamin D supplements. Infants respond to discontinuation of vitamin D supplements. These occurrences have prompted vitamin reformulation of preterm nutritional products. Laboratory studies in hypervitaminosis D typically show elevated $25(\text{OH})\text{D}$ levels but not $1,25(\text{OH})_2\text{D}$ levels and suppressed serum PTH levels.

Hypervitaminosis A, caused by renal failure or ingestion of a large amount of vitamin A, has been associated with hypercalcemia. It is hypothesized that vitamin A inhibits osteoblasts and stimulates osteoclasts, leading to increased bone turnover (Clark and Smith, 1964; Bush and Dahms, 1984).

Hypercalcemia has also been reported in neonates receiving extracorporeal life support (ECLS). The mechanism is not well understood. High PTH level has been reported but does not seem to correlate well with the calcium and vitamin D levels. Hypercalcemia was associated with higher mortality and longer duration of ECLS (Fridriksson et al., 2001; Rambaud et al., 2015).

Other Causes of Neonatal Hypercalcemia

Tumor-associated hypercalcemia in neonates is extremely rare. Congenital mesoblastic nephroma has been associated with hypercalcemia in infancy and may be due to tumor secretion of PTHrP (Srivastava et al., 2011). Metabolic disorders, congenital lactase deficiency, and congenital sucrose–isomaltase deficiency are associated with hypercalcemia. Infants will also have symptoms of persistent diarrhea and failure to thrive. The hypercalcemia may be due to increased ileal absorption of calcium as well as effects of metabolic acidosis on release of calcium from bone (Saarela et al., 1995; Belmont et al., 2002). Immobility can also cause hypercalcemia because of increased bone turnover (Vyas et al., 2016).

Blue diaper syndrome is a rare familial disease in which hypercalcemia and nephrocalcinosis are associated with a defect in the intestinal transport of tryptophan (Drummond et al., 1964). Bacterial degradation of tryptophan in the intestine leads to excessive production of indole, which is converted to indican in the liver. Oxidative conjugation of indican in the urine forms the water-insoluble dye indigo blue (indigotin), with a consequent peculiar bluish discoloration of the diaper. The clinical course is characterized by failure to thrive, recurrent unexplained fever, infections, marked irritability, and constipation.

Hypophosphatasia is a rare autosomal recessive condition caused by mutations in the tissue nonspecific ALP because of mutations

in *ALPL*. Laboratory tests will show very low ALP levels. Depending on the age at diagnosis, six clinical forms are currently recognized: perinatal (lethal), perinatal benign, infantile, childhood, adult, and odontohypophosphatasia. Prominent features of the early-onset severe forms include respiratory complications, increased intracranial pressure, widespread undermineralization, rickets, and hypercalcemia (Mornet and Nunes, 2007).

Treatment

Treatment will depend on the cause and severity of hypercalcemia. If the hypercalcemia is mild to moderate, then restriction of calcium and vitamin D may be sufficient. In more severe cases, further steps must be taken. Part of the treatment is rehydration. Hydration with normal saline is recommended to help induce sodium diuresis and increase urine calcium excretion. Once adequate rehydration with adequate urine output has been established, a loop diuretic such as furosemide (1 mg/kg intravenously at 6- to 8-hour intervals) may be added as it inhibits calcium reabsorption. Hydrocortisone reduces calcium absorption in the intestine and can be given as 1 mg/kg every 6 hours. Calcitonin decreases skeletal reabsorption and inhibits renal reabsorption of calcium. Subcutaneous or intramuscular doses of 3 to 6 µg/kg every 6 hours can be given, but this is only effective for a few days as tachyphylaxis will occur. Bisphosphonates such as pamidronate have been used successfully in a number of hypercalcemic conditions. These agents inhibit osteoclasts and bone resorption. Pamidronate doses of 0.5 to 2 mg/kg have been reported. Cinacalcet is a calcimimetic that works to make CaSR more sensitive. It has been used in cases of *CaSR* mutations.

Neonatal Disorders of Serum Magnesium

Neonatal hypomagnesemia was discussed in Neonatal Hypocalcemia Associated With Hypomagnesemia or Renal Tubular Acidosis.

Neonatal hypermagnesemia is usually due to maternal magnesium sulfate administration or postnatal excess administration of magnesium-containing products including magnesium in neonatal parenteral nutrition solutions that exceeds magnesium clearance, use of magnesium hydroxide-containing antacids (e.g., milk of magnesia), or medication errors resulting in overadministration of magnesium. Magnesium inhibits acetylcholine release at neuromuscular junctions; therefore elevated levels will lead to symptoms of low tone in mild cases to paralysis in severe cases. The hypermagnesemic newborn may exhibit central nervous system depression (lethargy, hypotonia, poor suck ability), hyporeflexia, and hypotension in mild to moderate cases. Severe cases may result in muscle paralysis, hypoventilation, respiratory depression, coma, arrhythmias, complete heart block, and asystolic arrest. As hypermagnesemia decreases myocardial electrical conduction, cardiac features may include prolonged PR, QRS, and QT intervals, intraventricular conduction defects, bradycardia, and peaked T waves. Because of effects on increased bowel motility, increased fluid secretion and electrolyte abnormalities may be seen; however, delayed passage of meconium has also been reported. In addition, hypocalcemia caused by inhibition of PTH by high levels of magnesium may also be seen. Treatment is mostly supportive as eventually the magnesium will be cleared by the kidney. Any administration of magnesium (oral or IV) should be discontinued. Regular monitoring for cardiac, respiratory, and electrolyte abnormalities should be done, and any abnormalities should be treated accordingly. Feedings should be deferred until normalization of bowel function occurs. Calcium infusions may be helpful in severe, symptomatic cases as calcium is an antagonist of magnesium. Hemodialysis may be

considered in life-threatening situations in anuric patients (Sullivan and Berman, 2000; Narchi, 2001).

Metabolic Bone Disease in Newborns and Infants

Metabolic bone disease (MBD) is characterized by the reduction in the mineral content and protein matrix of bone, frequently manifesting itself with rachitic changes. MBD is common in premature infants and has also been referred to as *osteopenia* and *rickets of prematurity*. The forms of MBD manifesting themselves in infants and children are listed in Box 95.3.

The following are terms commonly used in describing MBD:

- *Osteopenia* is generally defined as diminished bone mineral density secondary to a reduction in the thickness of bone cortex and trabeculae.
- *Osteoporosis* is defined in pediatrics as a reduction in bone mineral density with clinically significant fractures (Gordon et al., 2014). Unlike in rickets and osteomalacia, in which mineralization defects predominate, the primary abnormality in osteoporosis is either a decrease in matrix formation or an increase in matrix and mineral resorption.
- *Rickets* results from undermineralization of the bone matrix, or osteoid, in growing bone; it involves both the growth plate (physis) and newly formed trabecular and cortical bone. In infancy, the most rapidly growing bones are the skull, upper limbs, and ribs. Early development of rickets therefore leads to craniotabes, characterized by softening of the skull with the “ping-pong ball” sign; widened cranial sutures; frontal bossing; swollen epiphyses of wrists; costochondral beading manifesting itself as a “rachitic rosary”; and Harrison sulcus, which is caused

by diaphragmatic depression of the lower thorax on inspiration. Manifestations of muscle weakness may include dilated cardiomyopathy and ventricular dysfunction, which respond to vitamin D therapy (Brown et al., 2009). Radiographic features in rickets result from expansion of the cartilaginous growth plate and delayed mineralization. They include lucency and widening of the gap between metaphysis and epiphysis, known as the *zone of provisional calcification*, as well as irregularity, cupping, or fraying of the metaphyseal margin. Serum phosphorus or calcium level or both are characteristically depressed, and serum ALP level is elevated. An exception is in the hyperphosphatemia of renal osteodystrophy.

- *Osteomalacia* is rickets that occurs in the absence of linear growth. This is the typical pattern in adults, but it may also occur in poorly nourished preterm infants. In osteomalacia, the radiographic features of rickets at the cartilage–shaft junction are generally absent.

Metabolic Bone Disease of Prematurity

MBD of prematurity is caused chiefly by deficiencies in dietary phosphate and calcium. Eighty percent of bone mineralization in the fetus occurs during the third trimester (Widdowson et al., 1951; Ellis et al., 1994), when fetal calcium and phosphorus requirements are 100 to 130 mg/kg per day and 60 to 75 mg/kg per day, respectively. Low mineral, especially phosphorus, containing diets do not meet the needs for bone mineralization of preterm infants and therefore predispose premature infants to this form of osteopathy. The greatest risks for phosphate deficiency result from (1) feeding unsupplemented human milk, (2) milk formulas not designed for use in preterm infants, or (3) prolonged parenteral nutrition. About 30% of preterm infants with birthweights less than 1500 g develop bone disease (Funke et al., 2006). The rates are thought to be higher still in infants with ELBW of less than 1000 g. Even close attention to nutrition support does not prevent a high prevalence of bone disease in ELBW infants (Mitchell et al., 2009).

Additional, nonnutritional risk factors for MBD in ill preterm infants include the early withdrawal of placental estradiol and progesterone, lack of mobility, and therapy with a variety of medications, including dexamethasone and methylxanthines (Box 95.4), which can increase urinary calcium excretion and contribute to serum mineral imbalance, nephrocalcinosis, and osteopenia (Aladangady et al., 2004). Glucocorticoids decrease bone formation by inhibiting osteoblast growth and increasing cell death of osteoblasts and osteocytes and, at least over several months, increasing osteoclastogenesis and bone resorption. Copper deficiency is a rare contributor to osteopenia in preterm infants (Olivares and Uauy, 1996).

• BOX 95.3 Forms of Metabolic Bone Disease Manifesting Themselves in Newborns and Infants

Phosphate Deficiency

- Osteopathy of prematurity
- X-linked hypophosphatemic rickets
- Fanconi syndrome
- Antacid-induced osteopathy (aluminum hydroxide)
- Tumor (including hemangioma)-associated rickets

Calcium Deficiency

- Osteopathy of prematurity
- Inadequate intake of dietary calcium after weaning
- Inadequate calcium in total parenteral nutrition solution

Vitamin D Deficiency

- Maternal vitamin D deficiency (congenital rickets)
- Inadequate intake of dietary vitamin D
- Lack of adequate sunlight exposure and dietary inadequacy

Vitamin D Malabsorption

- Hepatic disease (steatorrhea)
- Short bowel syndrome
- Pancreatic insufficiency

Vitamin D Metabolic Defects

- Hepatic rickets (inadequate vitamin D 25-hydroxylation)
- 1 α -Hydroxylase deficiency
- Renal insufficiency (renal osteodystrophy)
- Anticonvulsants (increased 25(OH)D metabolism)

Vitamin D Receptor Defects

- Hereditary vitamin D resistance

• BOX 95.4 Medications Associated With Metabolic Bone Disease in Preterm Infants

- Glucocorticoids
- Furosemide/loop diuretics
- Methylxanthines
- Anticonvulsants: phenytoin and phenobarbital
- Antacids: proton pump inhibitors and H₂ blockers
- Anticoagulants
- Cyclosporine

In preterm infants, osteopenia with or without rachitic changes at the cartilage–shaft junction usually appears between 6 and 12 weeks of age, and fractures are reported in up to 24% in VLBW infants (Eliakim and Nemet, 2005). The incidence and severity increase with decreasing gestational age and birthweight, and they are more common in preterm infants with a complicated medical course and delayed nutrition. In VLBW babies, postnatal bone mineralization significantly lags behind the expected intrauterine bone mineralization rate. The pathogenesis involves increased endosteal resorption more than decreased bone formation—that is, it is a high-turnover osteopathy (Beyers et al., 1994). On the other hand, osteopathy is usually not a problem for healthier, larger preterm infants.

Clinical Findings of Metabolic Bone Disease of Prematurity

The clinical findings in VLBW infants with severe osteopathy, as in older, term infants with rickets, include a widened anterior fontanel, craniotabes, bony expansion of wrists, costochondral beading, and rib or long-bone fractures. Rib undermineralization, softening, and fractures can lead to respiratory distress (especially tachypnea), atelectasis, or pneumonia. Long-term effects of osteopathy of prematurity may include delayed dental maturation (Seow, 1996) and reduced height and bone mineral density in adulthood (Hovi et al., 2009).

Mineral Deficiency in Metabolic Bone Disease

Phosphate depletion and osteopathy occur in rapidly growing preterm infants fed unsupplemented human milk, which has low phosphate content. Characteristically, these infants develop hypophosphatemia, hypophosphaturia, hypercalcemia, and hypercalciuria. Serum PTH level may be low or normal, 25(OH)D level is normal, and 1,25(OH)₂D level is elevated. The hypophosphatemia stimulates production of 1,25(OH)₂D, which in turn increases intestinal calcium absorption. However, in the presence of hypophosphatemia, only limited amounts of calcium can be deposited in bone, leading to hypercalcemia and hypercalciuria. The hypercalcemia inhibits PTH secretion.

This form of osteopathy does not respond to vitamin D therapy unless vitamin D deficiency also is present. Vitamin D supplementation without prior correction of the underlying dietary phosphate deficiency may aggravate hypercalcemia and hypercalciuria by enhancing intestinal calcium absorption. The bone disease in these infants responds to increased dietary phosphate, accomplished by addition of a human milk supplement designed for preterm infants or by the switching to a preterm milk formula; both diets provide additional calcium as well as phosphorus. The recommendations for enteral nutrition for VLBW infants for phosphate and calcium range from 75 to 140 mg/kg per day and from 150 to 220 mg/kg per day, respectively (Abrams and Committee on Nutrition, 2013). The addition of 20 to 25 mg/kg per day of potassium phosphate may also be required for repletion of deficient serum phosphorus levels. However, because phosphate repletion promotes bone mineralization, serum calcium level may fall to subnormal levels (“hungry bones” syndrome) unless supplemental calcium (e.g., 30 mg/kg per day) also is provided. The recommended intakes of calcium and phosphorus (Demarini, 2005) have benefits of improved bone growth, less severe dolichocephaly, and avoidance of fractures. For infants with a history of osteopathy of prematurity, it is important that after hospital discharge a mineral-enriched diet

and serial laboratory monitoring be maintained for several weeks to months.

Most often, neither hyperparathyroidism nor vitamin D deficiency is present in phosphate-deficient osteopathy of prematurity. In contrast, the pathogenesis of calcium-deficiency rickets and that of vitamin D deficiency are similar in that hypocalcemia causes hyperparathyroidism. The elevated PTH level increases bone resorption and enhances renal 1,25(OH)₂D synthesis, which, in turn, increases intestinal calcium and phosphorus absorption. Individual preterm babies may have predominant phosphate depletion, but mixed phosphate and calcium deficiency is more common; isolated calcium deficiency is rare. In dual-mineral deficiency, laboratory tests may show low, normal, or slightly elevated serum calcium levels and low to low-normal phosphorus levels. In cases of severe or complicated bone disease, serum 25(OH)D is a useful screen for evaluation of sufficiency of vitamin D stores; levels less than 6 ng/mL indicate *severe* vitamin D deficiency (Misra et al., 2008).

Imaging for Metabolic Bone Disease

For evaluation of bone mineral status in preterm neonates, measurement of bone cortical thickness and visual inspection of the proximal part of the humerus on a chest radiograph is a common screen for bone disease. Additional images may be required to fully assess the neonate for MBD (Fig. 95.2). However, the appearance of “osteopenia” may not be appreciated on plain film until a 20%–40% decrease in mineralization is reached (Nelson and Koo, 1999). For that reason, assessment of bone mineral content by dual X-ray

• **Fig. 95.2** The long bones in this 6-week-old ex-26-week infant demonstrate severe generalized osteopenia. The zones of provisional calcification are frayed and very irregular. The metaphyses are irregular, showing cupping and fraying, particularly prominent at the knees and distal part of the femurs.

absorptiometry (DXA) may be used for its accuracy, reproducibility, and low radiation exposure. Normative data remain somewhat limited in preterm and former preterm infants, decreasing DXA's utility (Abrams and Committee on Nutrition, 2013). Longitudinal quantitative ultrasound measurement of the speed of sound in long bones, combined with measurement of serum bone markers, is a promising assessment tool (Ashmeade et al., 2007) although not one commonly used clinically at this time. Use of quantitative computed tomography to assess true volumetric bone density is limited by its significantly higher radiation exposure and lack of normative data in infants.

Laboratory Evaluation

Serum ALP, a marker of osteoblastic bone formation, is frequently used to monitor skeletal metabolism in preterm infants. However, the magnitude of elevations in ALP concentrations is not a good predictor of the extent of bone mineral deficits. As elevations of ALP concentrations and clinical metabolic bone disease are rare in the first 4 weeks of life, the American Academy of Pediatrics Committee on Nutrition recommends ALP and serum phosphorus concentrations be measured at 4 to 6 weeks after birth in VLBW infants and biweekly thereafter. The ALP concentration usually peaks at 400 to 800 IU/L and then decreases in VLBW infants who do not develop MBD (Abrams and Committee on Nutrition, 2013).

Use of PTH has been suggested (Moreira et al., 2014) as an early marker of MBD in preterm infants. Moreira et al. (2014) reported that a PTH level greater than 180 mg/dL at 3 weeks' chronologic age should alert clinicians to the possibility of MBD. Serial urinary biomarkers of bone metabolism (e.g., pyridinoline, deoxypyridinoline) have not yet been shown to be useful in predicting severe osteopathy because the levels are related to bone volume, and normative data for growing preterm infants are lacking.

Vitamin D–Deficiency Rickets

Vitamin D-deficiency rickets most often occurs in exclusively breastfed infants who also have little exposure to sunlight and are dark skinned. Unfortified human milk has a vitamin D activity ranging from 5 to 80 IU/L (Specker et al., 1985; Greer, 2004; Hollis et al., 2015), which may be insufficient for maintaining normal 25(OH)D levels in infants. Historically, a marked rise in the prevalence in nutritional rickets has accompanied industrialization and urban crowding. Clinical rickets often manifests itself at 3 months of age or later, but onset in early infancy is not uncommon. In developed countries, nutritional rickets has never been eradicated, and there is a resurgence of vitamin D deficiency in North America and Europe (Rovner and O'Brien, 2008). As reviewed, maternal vitamin D deficiency during pregnancy and lactation puts the newborn at high risk. There are long-term deleterious effects on musculoskeletal health (Nabulsi et al., 2008). The 2008 American Academy of Pediatrics statement on prevention of rickets and vitamin D deficiency (Wagner et al., 2008) doubles the previous American Academy of Pediatrics vitamin D intake recommendation. These guidelines state that breastfed and partially breastfed infants should receive supplementation with 400 IU vitamin D per day beginning in the first few days of life. All infant formulas available in the United States must contain at least 400 IU/L vitamin D. Consequently, the guidelines also state all nonbreastfed infants who are ingesting less than 1 L of formula per day should receive a vitamin D supplement of 400 IU/day.

In 2013 the American Academy of Pediatrics Committee on Nutrition recommended that VLBW infants receive 200 to 400 IU vitamin D per day. This can be increased to 400 IU/day when the weight exceeds 1500 to 2000 g and the infant is tolerating full enteral nutrition (Abrams and Committee on Nutrition, 2013). European guidelines suggest higher intakes of vitamin D of 800 to 1000 IU/day may be used for VLBW infants (Agostoni et al., 2010).

Higher doses of vitamin D may be necessary for infants with fat malabsorption or those taking anticonvulsant medications. Vitamin D status should be assessed with use of 25(OH)D and PTH concentrations and measures of bone mineral status. Stoss therapy, which occasionally is used to treat rickets, consists of a single large oral or intramuscular dose (150,000–500,000 IU) of vitamin D (Emel et al., 2012).

Nutritional rickets worldwide can be due to degrees of vitamin D deficiency or calcium deficiency. Calcium deficiency is the major cause of rickets in Africa and some parts of tropical Asia but is being recognized increasingly in other parts of the world (Thacher et al., 2006). As a consequence, in tropical populations, rickets may occur later than at higher latitudes, between 1 and 2 years of age, after weaning, and with introduction of a low-calcium diet. One study showed, for example, that in Turkey most rachitic children had vitamin D deficiency, whereas in Egypt they had mostly calcium insufficiency combined with vitamin D deficiency (Baroncelli et al., 2008). It is likely that relative deficiencies of calcium and vitamin D interact with genetic (e.g., vitamin D receptor genotypes) and/or environmental factors to stimulate the development of rickets. Therefore the current North American and European recommendations for vitamin D supplementation may need adjustments for other pediatric populations with limited calcium intake.

Congenital rickets should always prompt an investigation for maternal vitamin D deficiency. Rickets, hypercalciuria, and hypophosphatemia also occur in Fanconi syndrome. Prolonged treatment with aluminum-containing antacids can induce hypophosphatemia and rickets (Pattaragarn and Alon, 2001). These antacids should be avoided or used with caution during infancy.

Renal Osteodystrophy

Because normal renal function is essential for physiologic mineral and bone metabolism, renal insufficiency induces hyperphosphatemia and bone disease. Renal osteodystrophy can be predominantly high or low bone turnover, or the two types may alternate during the clinical course in an individual infant (Levin and Stevens, 2014). High bone turnover or osteitis fibrosa is a manifestation of secondary hyperparathyroidism. Parathyroid hyperfunction often occurs early in the course of renal failure. Contributing factors include phosphate retention, impaired renal 1,25(OH)₂D synthesis, hypocalcemia, parathyroid gland hyperplasia, and skeletal resistance to PTH actions. Low-turnover osteodystrophy (adynamic bone or osteomalacia) results from suppressed bone formation; it is a major concern in the treatment of dialyzed infants.

A principal goal of therapy is to lower serum phosphate level so as to prevent hypocalcemia and severe hyperparathyroidism (Dasgupta et al., 2013). Phosphate restriction is accomplished by the feeding of breast milk or Similac PM 60/40. Oral phosphate binders such as calcium carbonate may be needed to reduce the intestinal absorption of phosphate. Hypocalcemia and metabolic acidosis should be treated with appropriate supplements. If serum 1,25(OH)₂D level is low, 1,25(OH)₂D therapy will increase

intestinal calcium absorption, transcriptionally suppress PTH gene expression, and decrease parathyroid hyperplasia. Serum calcium, phosphorus, and PTH levels, as well as linear growth and bone radiographs, should be serially monitored (Kemper and van Husen, 2014). Management of severe renal osteodystrophy in neonates is particularly complicated by increased phosphate requirements for growth. Calcium supplementation and use of potent vitamin D metabolites may also produce an “oversuppression” of PTH, contributing to adynamic bone disease. As with any complex disorder, effective clinical management requires close monitoring and an integrated team approach.

Inherited Metabolic Bone Disease in Infancy

Several forms of MBD or rickets have been described that can present in newborns and infants (DiMeglio and Econs, 2001). 1α -Hydroxylase deficiency, formerly known as *vitamin D-dependent rickets type 1*, is caused by a mutation in the gene encoding 25(OH) D 1α -hydroxylase (*CYP27B1*) (Wang et al., 1998). This autosomal recessive disorder is associated with defective conversion of 25(OH) D to $1,25(\text{OH})_2\text{D}$ and is most common in French-Canadian kindreds. Muscle weakness with severe hypocalcemia and secondary hyperparathyroidism appear shortly after birth, and rickets presents within the first year of life. Treatment with 1α -hydroxylated vitamin D analogues induces remission.

Hereditary resistance to vitamin D, formerly known as *vitamin D-dependent rickets type 2*, is caused by mutations in the vitamin D receptor gene. This mutation leads to end-organ resistance to $1,25(\text{OH})_2\text{D}$. Affected infants show early-onset rickets, hypocalcemia, elevated serum $1,25(\text{OH})_2\text{D}$ levels, secondary hyperparathyroidism, and alopecia. Depending on the genotype, there is a variable response to supraphysiologic doses of $1,25(\text{OH})_2\text{D}$ analogues and calcium.

X-linked dominant hypophosphatemia (XLH), also known as *familial hypophosphatemic rickets*, is a disorder of phosphate homeostasis (Gattineni, 2014). Its prevalence is 1 in 20,000. XLH is characterized by hypophosphatemia, rickets, and poor linear growth and is associated with a low TmP and renal tubular phosphate leak. Defective regulation of vitamin D metabolism results in inappropriately normal $1,25(\text{OH})_2\text{D}$ concentrations in the face of hypophosphatemia. XLH is caused by mutations in the phosphate-regulating endopeptidase homologue, X-linked gene (*PHEX*). Treatment consists of supplemental phosphate and calcitriol, with the goal of normalizing the ALP level, keeping the PTH level normal, maximizing linear growth, and reducing rachitic changes. There is a similar condition of autosomal dominant hypophosphatemic rickets caused by an activating mutation in the fibroblast growth factor 23 gene (*FGF23*) on chromosome band 12p13. Treatment is similar to that for XLH. Autosomal recessive hypophosphatemic rickets type 1 and autosomal recessive hypophosphatemic rickets type 2 are caused, respectively, by mutations in the dentin matrix acidic phosphoprotein 1 gene (*DMP1*) and the ectonucleotide pyrophosphatase/phosphodiesterase 1 gene (*ENPP1*), which interfere with bone mineralization and renal phosphate handling.

Osteogenesis imperfecta (OI) is a heterogeneous group of disorders that cause various degrees of bone fragility and skeletal

deformity (Forlino and Marini, 2016). OI was originally identified as an autosomal dominantly inherited abnormality of type I collagen due to mutations of *COL1A1* and *COL1A2*. Four primary types were initially described. However, in the past several years, several other types have been identified, most of which have autosomal recessive inheritance. The most severe forms present with fractures at or shortly after birth. The affected babies may also have deformities of long bones, osteopenia of the skull, and early death due to respiratory deficiency. Administration of a bisphosphonate such as pamidronate may help reduce bone fractures and bone pain (Glorieux et al., 1998).

Hypophosphatasia is characterized by defective bone mineralization secondary to deficiency of the tissue-nonspecific isoenzyme of ALP. It is caused by a mutation of the *ALPL* gene on chromosome band 1p36. Perinatal lethal, infantile, childhood, and adult-onset forms have all been described, with the most severe forms being the perinatal and infantile forms. Clinical manifestations in infants include osteomalacia and rickets with respiratory insufficiency due to progressive chest deformity. Hypercalcemia and hyperphosphatemia can be seen in severely affected infants. Whyte et al. (2012) showed that enzyme replacement with recombinant ALP can improve skeletal findings as well as pulmonary and overall physical function in infants with the perinatal and infantile forms of hypophosphatasia.

Neonatal rickets with increased bone density rather than osteopenia can occur in infantile osteopetrosis, a rare autosomal recessive disorder of osteoclast formation. Diagnosis may be obscured by concurrent maternal vitamin D deficiency (Popp et al., 2000).

Disorders of the Adrenal Gland

PATRICIA Y. FECHNER

KEY POINTS

- Infants born with ambiguous genitalia or nonpalpable testes need to be evaluated for congenital adrenal hyperplasia as it can be life threatening.
- Adrenal steroid levels vary with gestational age.
- Adrenal insufficiency should be treated with hydrocortisone to avoid adrenal crisis. High doses of hydrocortisone contain mineralocorticoid activity.

The Adrenal Gland

Embryology

Normal adrenal function is critically important for maintenance of intrauterine homeostasis, promotion of organ maturation, and adaptation to extrauterine life. The dual embryologic origin of the human adrenal gland results in an outer adrenal cortex and an inner adrenal medulla; each part secretes different vital hormones critical to fetal development. Embryologically, the adrenal cortex develops from the coelomic mesoderm of the urogenital ridge, whereas the medulla arises from neural crest tissue in the adjacent sympathetic ganglion at celiac plexus level. During the 5th week of fetal development, mesothelial cells from the posterior abdominal wall, between the root of the bowel mesentery and developing mesonephros, proliferate and form the primitive adrenal cortex. In the 6th week, a second wave of mesothelial cells surrounds the primitive cortex and later forms the adult or definitive cortex. By 8 weeks of gestation, the cortical mass separates from the rest of mesothelial tissue and becomes surrounded by connective tissue (Sadler, 2000). This separation divides adrenocortical and gonadal primordium (Mesiano and Jaffe, 1997). Chromaffin cells, which originate from neural crest, migrate toward the adrenal cortex around this time and gradually invade the medial aspect of the cortical tissue along its central vein to gain central position, forming the adrenal medulla. Fig. 96.1 summarizes the embryologic origin of the adrenal gland (Else and Hammer, 2005). By 8 to 9 weeks of gestation, the adrenal gland is encapsulated and contains an outer “definitive” zone where glucocorticoids and mineralocorticoids are synthesized and a larger inner “fetal” zone where dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS) are produced and then subsequently converted to estriol by the placenta. Postnatally, the fetal or primitive zone of the adrenal gland rapidly involutes to disappear by approximately 6 months of age (Kempna and Fluck, 2008). Zonation of the cortex,

zona glomerulosa, and fasciculata is present at birth, but full differentiation into three separate zones occurs much later, at approximately 3 years of age, when zona reticularis development takes place (Barwick et al., 2005). Fig. 96.2 depicts these changes in the adrenal gland from 9 weeks of gestation through childhood. This chapter focuses on the development, function, and pathophysiology of the steroidogenic adrenal cortex.

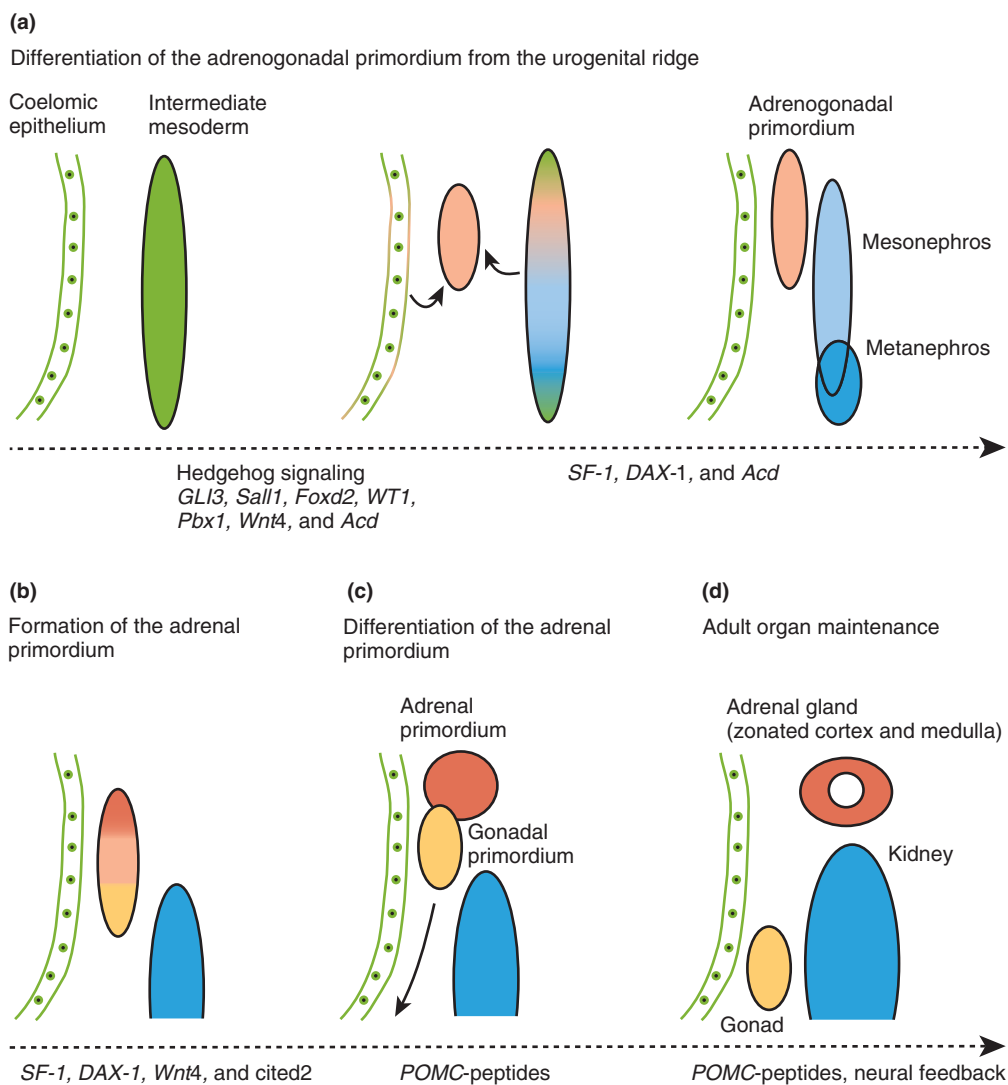

Morphology

The adrenal glands are bilateral structures, located above the kidneys in the retroperitoneum area. At birth, the adrenals are approximately one-third the size of neonatal kidneys, weighing 8 to 9 grams, and are 10- to 20-fold larger than the adult glands relative to body weight (0.4% vs 0.01%) (Moore and Persaud, 1998). In the third trimester and the first 3 months after birth, the glands predominantly consist of cortex, where active production of glucocorticoids, steroid precursors, estrogens, and progesterone takes place. Ultrasonographically, the neonatal adrenal gland characteristically has a thin reflective core surrounded by a thick transonic zone. The gland subsequently decreases in size as the active fetal cortex regresses to reach approximately 8% of the kidney size in adulthood (Barwick et al., 2005).

Histologically, the fetal adrenal cortex consists of a small outer definitive zone, which appears to produce few adrenal steroid hormones until late gestation, and a larger inner fetal zone that produces adrenal steroid hormones throughout gestation. In addition, there is a transitional zone where cortisol production takes place toward the end of fetal development (Mesiano and Jaffe, 1997). At birth, the large fetal zone of the fetal adrenal involutes and disappears by 6 months of age. Concurrently, the definitive zone together with the transitional zone develops into the fully differentiated zona glomerulosa and fasciculata by the age of 3 years. The zona reticularis begins to develop only after 4 years of age and may not be fully differentiated before the age of 15 years. In an adult adrenal gland, these three distinctive zones lie adjacent to one another. The zona glomerulosa is located immediately below the capsule, the zona fasciculata being in the middle, and the innermost zone next to the medulla is the zona reticularis.

Fetal and Adult Adrenal Functions

A cascade of adrenal steroidogenesis in the adult is shown in Fig. 96.3. Three major pathways of mineralocorticoid, glucocorticoid, and androgen synthesis take place mainly in the glomerulosa, fasciculata, and reticularis zones of the cortex, respectively. Aldosterone is the main mineralocorticoid regulating sodium and fluid

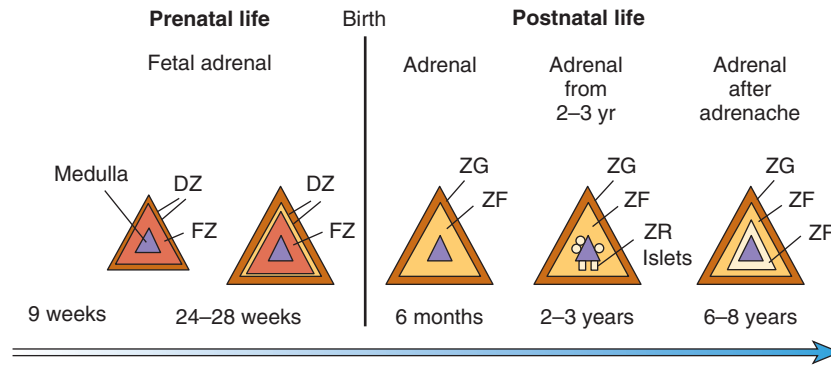

TRENDS in Endocrinology & Metabolism

• **Fig. 96.1** Adrenocortical Development From Urogenital Ridge to Adrenal Gland. *DAX-1*, Dosage-sensitive sex reversal-adrenal hypoplasia congenita critical region on the X chromosome gene-1; *POMC*, proopiomelanocortin; *SF-1*, steroidogenic factor-1. volume homeostasis; it is under the control of the rennin–angiotensin system and blood potassium concentrations (Kuhnle et al., 1981). The principal glucocorticoid in humans is cortisol and has a wide range of roles in regulating body functions, from carbohydrate metabolism, immune system, and acute and chronic stress response to musculoskeletal metabolism. Cortisol production is regulated through a negative feedback loop involving hypothalamic corticotropin-releasing hormone (CRH) and pituitary adrenocorticotrophic hormone (ACTH) (New and Wilson, 1999). Adrenal androgens have an age-specific secretion profile with an increase at adrenarche, which occurs 2 years before the time of puberty, and then a gradual decrease with aging until andropause (Orentreich et al., 1984). The regulatory mechanism behind normal adrenal androgen production is largely unknown but involves ACTH to some extent (Hanley and Arlt, 2006).

In the fetal adrenal gland, steroidogenic enzymes are found as early as 7 weeks' gestation (Goto et al., 2006; Hanley and

Arlt, 2006). At 8 weeks' gestation, the fetal adrenal gland produces cortisol under ACTH control. A transient expression of 3β -hydroxysteroid dehydrogenase type 2 (3β -HSD2) during this critical time from 7 to 12 weeks' gestation allows the fetal adrenal gland to produce cortisol. Activation of 3β -HSD2 serves principally to prevent virilization of the female genital anlage that would otherwise result from overwhelming amounts of DHEAS and its downstream androgen metabolites. It is believed that a transient peak of cortisol during this time suppresses the fetal hypothalamic–pituitary–adrenal (HPA) axis, keeping DHEAS production at a low level (Goto et al., 2006; White, 2006). By the end of the first trimester, cortisol secretion from the fetal adrenal gland begins to wane as a result of a decrease in 3β -HSD2 expression, thus decreasing HPA axis suppression with resultant increased DHEAS secretion. During the second and third trimesters, the fetal adrenal gland secretes abundant amounts of DHEA and its sulfated derivative DHEAS, earning

DZ, Definitive zone; FZ, fetal zone; ZG, zona glomerulosa; ZR, zona reticularis; ZF, zona fasciculata. (Adapted from Stewart PM, Newell-Price JDC. The Adrenal Cortex. In: Melmed S, Polonsky KS, Larsen PR, Kronenberg HM (eds). *Williams Textbook of Endocrinology*. 13th ed. Philadelphia, PA: Elsevier, Inc.; 2016: 489–555.)

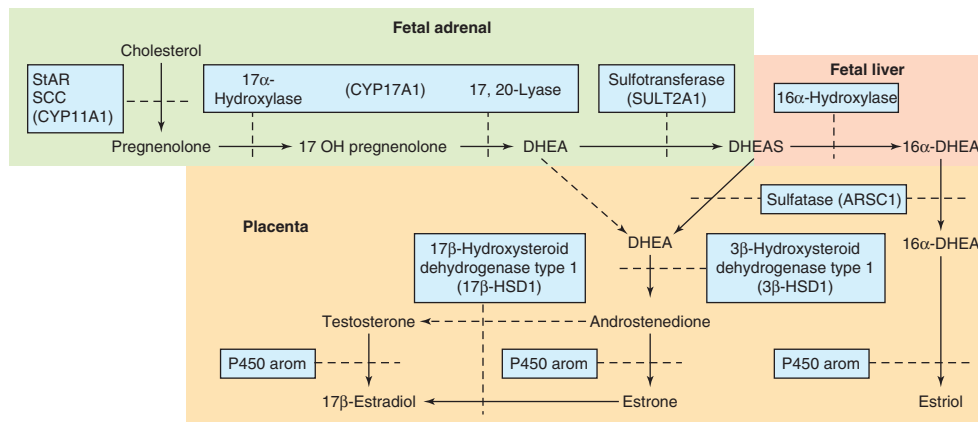

• **Fig. 96.3** Steroidogenesis of the Adult Adrenal Gland. Each of the three biosynthetic pathways takes place in different zones: aldosterone biosynthesis in the zona glomerulosa, cortisol biosynthesis in the zona fasciculata, and androgen production in the zona reticularis. The enzymes that catalyze the reactions are indicated in boxes.

the term *androgen factory* (Kempna and Fluck, 2008). The rate of steroid secretion by the fetal adrenal glands may be fivefold that of the adult adrenal glands at rest (Carr and Simpson, 1981). The placenta can also convert DHEAS back to DHEA by a sulfatase enzyme (i.e., arylsulfatase). These adrenal steroids serve as precursors for 17,20 lyase activity of the P450C17 enzyme for androgen production and subsequent estrogen production (Fig. 96.4). In addition, DHEAS is oxidized in the fetal liver to a 16 α -hydroxylated derivative, which is converted by the placenta to estriol by the same set of enzymes as in estradiol synthesis.

The physiology of human pregnancy involves a continuous supply of relatively increased amount of estrogens. In near-term human pregnancy, the rate of estrogen production increases strikingly, reaching concentrations 1000-fold greater than that of nonpregnant women (Carr and Simpson, 1981). During early gestation, the estradiol required to maintain pregnancy is provided

by the corpus luteum of the maternal ovary. But after 8 weeks' gestation, the fetoplacental unit synthesizes most of the estradiol required to maintain pregnancy (Simpson and MacDonald, 1981).

DHEAS is the main steroid secreted by the fetal adrenal cortex from midgestation onward. The activity of 3 β -HSD2 controls fetal cortisol synthesis. By the end of pregnancy, fetal cortisol is required in preparation for parturition (i.e., lung maturation or surfactant production) and could have a role in triggering parturition, as shown in other species (Gross et al., 2000). Maternal cortisol cannot normally reach the fetus because it is oxidized to cortisone, an inactive steroid, by placental 11 β -hydroxysteroid dehydrogenase type 2 (Wilson et al., 2001). When pregnancy approaches term, 3 β -HSD2 expression increases again and remains high, allowing increased cortisol secretion. In a child, 3 β -HSD2 secretion is high in the adrenal gland until adrenarche, when 3 β -HSD2 activity decreases again to allow an increase in DHEA (Gell et al., 1998).

• **Fig. 96.4** Steroidogenesis of the Fetal Adrenal Gland and Fetoplacental Unit. Predominant dehydroepiandrosterone and dehydroepiandrosterone sulfate production occurs after 12 weeks' gestation. DHEA, Dehydroepiandrosterone; DHEAS, dehydroepiandrosterone sulfate; SCC, side chain cleavage of cholesterol; StAR, steroidogenic acute regulatory protein.

and its downstream androgen metabolite secretion, which gives rise to the development of pubic and axillary hair.

Control of Glucocorticoid and Mineralocorticoid Production

Two distinct regulatory circuits control adrenal glucocorticoid and mineralocorticoid secretion. The HPA axis determines the set point for circulating glucocorticoid (cortisol) concentration. The neuropeptide CRH (or factor) and arginine vasopressin (AVP) are synthesized in the hypothalamic paraventricular nucleus and released into the hypophyseal portal circulation at the median eminence in response to stress (Aguilera, 1994) and, beginning at approximately 6 months of age, to circadian cues (Onishi et al., 1983). These neuropeptides stimulate the release of ACTH from the anterior pituitary corticotrophs. CRH is the primary stimulator of ACTH while AVP amplifies the effect of CRH. ACTH released into the systemic circulation augments adrenocortical secretion of cortisol and DHEA by acting on the ACTH receptor (Clark and Cammas, 1996), a member of the melanocortin receptor family. The ACTH receptor is present on steroidogenic cells of the fetal zone and transitional zone of the fetal adrenal as well as the adult adrenal cortex. The resulting increase in plasma cortisol concentration limits further release of hypothalamic neuropeptides and ACTH by negative feedback through glucocorticoid receptors at the central nervous system and pituitary sites. As a corollary, if glucocorticoid production is impaired by intrinsic adrenal dysfunction, then neuropeptide CRH and ACTH release are augmented.

The components of the HPA axis are present early in human development (Mesiano and Jaffe, 1997). As detailed earlier, the fetal adrenal gland begins to develop at 4 weeks' gestation, when initial evagination of the pituitary primordium occurs (Conklin, 1968). ACTH-producing pituitary cells can be detected at 7 weeks' gestation, and an intact hypophyseal portal vascular system is present by 12 weeks' gestation (Baker and Jaffe, 1975; Thliveris and Currie, 1980). Nerve terminals containing CRH can be detected in the hypothalamus by approximately 16 weeks' gestation. Virilization caused by increased production of adrenal androgens in females with congenital adrenal hyperplasia (CAH) occurs before 12 weeks' gestation; therefore ACTH-producing corticotrophs must undergo cortisol-mediated feedback modulation at the initial stages of hypothalamic–pituitary development (White, 2006).

Mineralocorticoid (aldosterone) release by the zona glomerulosa of the adrenal cortex is determined by the renin-angiotensin system, with acute modulation to a lower extent by ACTH as well (Dzau, 1988). Decreases in vascular volume result in increased secretion of renin by the renal juxtaglomerular apparatus. Renin, a proteolytic enzyme, cleaves angiotensinogen to angiotensin I, a biologically inactive decapeptide. Angiotensin I is then cleaved and activated by angiotensin-converting enzyme in the lung and other peripheral sites to angiotensin II. Angiotensin II and its metabolite angiotensin III possess vasopressor and potent aldosterone secretory activity. Although angiotensin II receptors are present on cells of the definitive zone at 16 weeks' gestation, significant aldosterone production by the fetal adrenal gland does not occur until the third trimester of pregnancy (Mesiano and Jaffe, 1997).

Molecular Basis of Adrenal Development

Several transcription factors are critically important for normal adrenal development. Two related transcription factors have emerged as key regulators of adrenal development: the nuclear receptor DAX-1 (dosage-sensitive sex reversal-adrenal hypoplasia congenita [AHC] critical region on the X chromosome gene-1, encoded by *NROB1/AHC*) and steroidogenic factor-1 (SF-1, encoded by *NR5A1*, also known as AD4BP). SF-1 (*Nr5a1*) knockout mice lack adrenal glands and gonads, and subsequent identification of *NR5A1* mutations in humans with adrenal insufficiency confirms the essential role of SF-1 in development (Parker, 1998). SF-1 (*Nr5a1*) expression is found in the early urogenital ridge of the mouse in cells that give rise to both the bipotential gonad and adrenal cortex. Expression of SF-1 (*Nr5a1*) remains high throughout embryogenesis, the postnatal period, and adult life (Parker, 1998).

DAX-1 is an orphan nuclear receptor that colocalizes with SF-1 in the cells of adrenal glands, gonads, gonadotropes, and ventral–medial lateral nucleus of the hypothalamus. Deletion of *NROB1* results in AHC. Although the exact role of DAX-1 in adrenal development is not known, it has been shown to interact with SF-1 (Ikeda et al., 2001). Normally, DAX-1 recruits the nuclear corepressor N-CoR to SF-1 and represses SF-1 (Crawford et al., 1998).

Similarly, the Wilms tumor suppressor gene (*WT1*) protein has been shown to interact with SF-1. *WT1* encodes 24 different protein isoforms that act as transcription factors. *Wt1* is detected

in the urogenital ridge of the mouse embryo but is not detected in adult or fetal adrenals. Mutations in *Wt1* have resulted in abnormal development of the adrenal in the mouse but have not been clearly correlated with abnormal human adrenal development (Vidal and Schedl, 2000). *WT1* has been found though to be expressed in the fetal adrenal gland (Ambu et al., 2015).

Assessing Adrenal Function in the Newborn

Significant evolution of adrenal steroid production occurs over the first days and months of life as the adrenal cortex plays a major role in the newborn postnatal adaptation. During interpretation of the newborn adrenal steroidogenic function, special attention must be paid to age-related changes in adrenal steroid intermediates, circulating cortisol, and aldosterone concentrations that reflect ongoing adrenal maturation (Sippell et al., 1978, 1980; Lashansky et al., 1991). For example, until at least 1 month postnatally, a large proportion of cortisol and its metabolites is excreted as sulfate esters. This sulfation may serve to inactivate a number of circulating cortisol metabolites during fetal and neonatal life (Ducharme et al., 1970).

Immediately after birth the third trimester fetal zone that once was the predominant component of the adrenal cortex in the fetus and preferentially produced DHEA and DHEAS starts to reduce in size. This rapid loss of the fetal zone during this period results in a dramatic fall of the circulating DHEA concentration over the 1st week to 1 month postnatally. The variable pattern of decline in the ensuing weeks probably reflects variation in remodeling of the fetal zone and emergence of the zona fasciculata of the definitive zone, the latter being a feature of an adult cortex. In addition to diminished 3β -HSD2 activity, preterm infants have sustained elevations in 17-hydroxyprogesterone and the 17-hydroxyprogesterone-to-cortisol ratio, suggesting a reduction in 21-hydroxylase activity (Lee et al., 1989; al Saedi et al., 1995). Because blood-spot 17-hydroxyprogesterone concentration is used for newborn screening of CAH in many states (White, 2009), many preterm infants initially have an abnormal test result. Subsequent follow-up testing is then required to determine whether CAH is present. Plasma aldosterone concentrations tend to be higher in preterm infants than in term infants, both of which in turn are higher than in older children and adults (Kotchen et al., 1972; Doerr et al., 1988).

Cortisol has a critical role in maintaining homeostasis in response to stress. Relative adrenal insufficiency occurs when the HPA axis produces less than adequate cortisol for the degree of illness or stress. Immaturity of the adrenal gland and the HPA axis of the premature newborn infant suggest a rationale for why preterm infants are at increased risk of cortisol insufficiency (Fernandez and Watterberg, 2009). Clinicians are commonly faced with critically ill infants who have cardiovascular insufficiency with hypotension, a condition that has been associated with adverse consequences. The question often arises as to whether these manifestations reflect underlying glucocorticoid insufficiency. There is increasing evidence that relative adrenal insufficiency may be a cause of hemodynamic instability and hypotension in the critically ill newborn, but there is definitely a paucity of data in this population.

Random plasma cortisol measurement is often inadequate to answer this question, because the majority of critically ill newborns have low cortisol and ACTH values, without the expected increase in response to critical illness. Infants also do not exhibit diurnal variation of ACTH and cortisol until 6 months of age. Thus obtaining two or more samples of cortisol may be informative.

Response to exogenous ACTH (cosyntropin) is usually normal, suggesting that the inadequate response to critical illness in these newborns does not result from adrenal dysfunction but arises from some other components of the HPA axis (Fernandez et al., 2008). Interestingly, in extremely low birthweight infants (500 to 999 g) low cortisol concentrations were not predictive of adverse short-term mortality and morbidity. In contrast, high basal cortisol levels were associated with severe intraventricular hemorrhage, and extremely elevated values were associated with morbidity and death (Aucott et al., 2008).

Data associating treatment of adrenal insufficiency with outcomes in the term newborn are limited, and there have been no studies on outcomes beyond the immediate neonatal period. Nonetheless, no adverse events have been attributed to glucocorticoid treatment based on a relatively small number of study subjects. Currently there is insufficient evidence to support the routine use of glucocorticoids in critically ill newborns. On encountering an infant with vasopressor-resistant hypotension, accompanied by signs of cardiac hypofunction, the clinician must consider the risk-to-benefit ratio before arriving at the appropriate management. Therapeutic trials with hydrocortisone at the dose of 1 mg per kilogram of body weight have been suggested (Fernandez and Watterberg, 2009) and can be discontinued if there is no clinical improvement or if the pretreatment cortisol level is later observed to be greater than 15 μ g/dL. A metaanalysis of the use of hydrocortisone for hypotension and vasopressor dependence in preterm infants showed improvement in blood pressure and less need for vasopressor, but the clinical benefit is unknown, and long-term effects of hydrocortisone use are not known (Higgins et al., 2010). Special attention should be paid to the premature newborn concurrently receiving indomethacin, because the combination of hydrocortisone and indomethacin is associated with spontaneous gastrointestinal perforation (Peltoniemi et al., 2005).

Primary Adrenal Disorders

Steroidogenic Defects Caused by Adrenal Enzyme Deficiency

CAH refers to a family of inherited disorders in which defects occur in one of the enzymatic steps required to synthesize cortisol from cholesterol in the adrenal gland; therefore impaired cortisol synthesis is the cornerstone shared by all forms of CAH. The pathway of steroidogenesis in the adrenal cortex is illustrated in Fig. 96.3. Five forms of CAH with autosomal recessive mode of inheritance are summarized in this section.

Disorders That Lead to Virilization in Females

21-Hydroxylase Deficiency

Pathophysiology. In 21-hydroxylase deficiency (21-OHD), which is responsible for 90%–95% of all CAH cases, the conversion of 17-hydroxyprogesterone (17-OHP), the main substrate of the 21-hydroxylase enzyme, to 11-deoxycortisol in the pathway of cortisol synthesis is impaired, and precursors are shunted through the androgen pathway. The enzyme defect also impairs the conversion of progesterone to aldosterone, causing abnormal salt loss (New et al., 1966; New and Seaman, 1970). There are two forms of classic 21-OHD: simple virilizing and salt-wasting, distinguished by the adrenal gland's ability to produce adequate aldosterone. In both forms, severe 21-OHD results in elevated levels of adrenal androgens that cause ambiguous genitalia in the genetic female fetus. Diagnosis is made by the detection of extremely high

TABLE 96.1 Adrenal Steroid Levels in Response to Adrenocorticotrophic Hormone for Various Ages

| Steroid | | Premature 26–28 Weeks' Gestation | Premature 34–36 Weeks' Gestation | 1–6 Months | <1 Year |
|---------------------------|------------|----------------------------------|----------------------------------|------------|---------|
| Androstenedione ng/dL | Baseline | 92–892 | 90–837 | 6–78 | 6–78 |
| | Stimulated | 145–1248 | 183–1367 | 21–114 | 21–139 |
| | Change | 40–718 | 13–1084 | 9–76 | 10–75 |
| Cortisol mcg/dl | Baseline | 1–11 | 3–34 | 3–22 | 3–23 |
| | Stimulated | 6–52 | 16–76 | 27–50 | 32–60 |
| | Change | 4–41 | 6–44 | 19–41 | 17–40 |
| Deoxycorticosterone ng/dl | Baseline | 20–105 | 28–78 | 7–48 | 7–57 |
| | Stimulated | 44–320 | 28–95 | 40–158 | 20–157 |
| | Change | 17–215 | 1–67 | 13–144 | 26–110 |
| 11-Deoxycortisol ng/dL | Baseline | 110–1376 | 70–455 | 10–200 | 10–200 |
| | Stimulated | 206–2504 | 81–645 | 101–392 | 80–390 |
| | Change | 15–1128 | 40–190 | 5–366 | 5–350 |
| 17-OH progesterone ng/dL | Baseline | 124–841 | 186–472 | 13–173 | 11–173 |
| | Stimulated | 285–1310 | 334–1725 | 85–250 | 85–466 |
| | Change | 50–596 | 18–1253 | 52–193 | 50–275 |

Data was obtained by extraction, chromatography, and RIA (Radioimmunoassay) method and may not be applicable to other methods. These values should be treated as approximate and not exact cutoffs. In the preterm infants, testing was done on postnatal days 2–4. Adapted with permission from Nakamoto JM, Mason PW (eds). *The Quest Diagnostics Manual. Endocrinology*. 5th ed. Madison New Jersey: Quest Diagnostics Incorporated; 2012.

concentrations of basal and stimulated 17-OHP after performing an ACTH stimulation test. Table 96.1 lists steroid levels at baseline and following 250 mcg of ACTH given as an intravenous (IV) bolus in infants at various ages. The diagnosis is confirmed by molecular genetic analysis of the *CYP21* gene.

Clinical Signs and Symptoms. Females with simple virilizing CAH can be diagnosed at birth immediately because of the apparent genital ambiguity (Prader, 1958). For newborn males, however, differentiation of the external genitalia is not affected, because the main source of testosterone is the testes and not the adrenal gland. Postnatally, genitalia may continue to virilize because of an excess of adrenal androgens, and pseudoprecocious puberty can occur. In affected females, signs of hyperandrogenism include facial, axillary, and pubic hair, adult body odor, temporal balding, severe acne, irregular menses, and reduced fertility. Poor control of adrenal androgens in males has been associated with small testes, infertility, and short stature. Infertility occurs because the excess androgens are aromatized peripherally to estrogens, which suppress pituitary gonadotropins and function of the gonads, and due to the development of testicular adrenal rest tumors. The high estrogens also advance bone age. The high levels of androgens can also accelerate growth in early childhood, producing an unusually tall and muscular child. Thus the patients are tall as children but short as adults. The salt-wasting phenotype, which occurs in approximately 75% of CAH cases (New and White, 1995), is biochemically distinct from the simple virilizing form because of a deficiency of aldosterone, the salt-retaining hormone (New et al., 1966; Nimkarn et al., 2007). Resulting hyponatremia, hyperkalemia, high plasma renin activity, and fluid volume depletion that occur at day 5 to 15 of life are potentially fatal.

Epidemiology. Newborn screening worldwide of almost 6.5 million babies has demonstrated an overall incidence of 1:15,000 live births for the classic form of 21-OHD (Pang et al., 1988; Pang and Clark, 1990, 1993). The incidence of classic CAH in

either homogeneous or heterogeneous general populations is as high as 1 case per 7500 live births (Speiser et al., 1985).

Molecular Genetics. Hormonally and clinically defined forms of 21-OHD CAH are associated with distinct genotypes characterized by varying enzyme activity demonstrated by in vitro expression studies. The gene encoding 21-hydroxylase is a microsomal cytochrome P450, family 21, subfamily A, polypeptide 21 (*CYP21A2*) located on the short arm of chromosome 6, within the human leukocyte antigen complex (Dupont et al., 1977; Nebert et al., 1991). *CYP21A2* and its homolog pseudogene *CYP21A1P* alternate with two genes, *C4B* and *C4A*, which encode two isoforms of the fourth component of the serum complement system (White et al., 1986). More than 100 mutations have been described to date. These mutations include point mutations, small deletions, small insertions, and complex rearrangements of the gene (Stenson et al., 2003). The most common mutations appear to be the result of two types of meiotic recombination between *CYP21A2* and *CYP21A1P*: (1) misalignment and unequal crossing over, resulting in large-scale DNA deletions, and (2) apparent gene conversion events that result in the transfer to *CYP21A2* of smaller-scale deleterious mutations present in *CYP21A1P*. It is not always possible to accurately predict the phenotype on the basis of the genotype; such predictions have been shown to be 79%–88% accurate (Speiser et al., 1992; Wedell et al., 1992; Wilson et al., 1995) with some nonconcordance. Studies have demonstrated that there is often a divergence in phenotypes within mutation-identical groups; the reason for this requires further investigation (Krone et al., 2000; Chemaitilly et al., 2005).

Management Issues. Hormone replacement therapy with corticosteroids is used to correct the deficiency in cortisol secretion, which will in turn suppress ACTH overproduction and subsequent stimulation of the androgen pathway (New and Wilson, 1999). Thus further virilization is prevented, allowing normal growth and onset of puberty. The dose of hydrocortisone

required is usually 15 to 20 mg/m² per day divided into three doses per day (Clayton et al., 2002; New et al., 2006) but may be even higher in the newborn. The dose can then be decreased to 10 to 15 mg/m² per day after there has been initial suppression of the ACTH–adrenal axis. It is important that the appropriate balance be maintained to avoid hypercortisolism, which can result in Cushing syndrome and suppression of linear growth. Attempts to suppress 17-OHP levels to normal will inevitably result in iatrogenic Cushing syndrome. Hormonal control can be difficult to achieve in some cases, and adrenalectomy may be offered as an extreme alternative therapeutic option in select patients (New, 1996; Van Wyk et al., 1996; Gmyrek et al., 2002). Patients with salt-losing CAH have elevated plasma renin activity and require mineralocorticoid replacement with 0.05 to 0.4 mg per day of 9 α -fludrocortisone. Neonates have mineralocorticoid resistance as evidenced by higher levels of aldosterone present in normal infants and thus the required dose of 9 α -fludrocortisone is higher in infants than in adults. In infancy, patients also require oral salt supplement as in other forms of primary adrenal insufficiency. There is no parenteral formulation for mineralocorticoid. Therefore if 9 α -fludrocortisone cannot be given orally, hydrocortisone at higher doses can be given IV along with sodium chloride. A dose of 20 mg of hydrocortisone will provide the equivalent of 0.1 mg 9 α -fludrocortisone. With the advent of newborn screening, infants are diagnosed with CAH prior to a salt-wasting crisis, and thus it is not possible to distinguish the infant with the 75% chance of having salt-wasting CAH without genetic testing. Because females with classic 21-OHD CAH are born with ambiguous genitalia caused by the production of excess androgens in utero, corrective surgery is contemplated. However, before surgical correction is considered as a form of treatment in patients with ambiguous genitalia, consultation with the patient's parents, psychologist, pediatric endocrinologist, and pediatric urologist is essential.

11 β -Hydroxylase Deficiency

Pathophysiology. The 11 β -hydroxylase deficiency (11 β -OHD) form of CAH represents 5%–8% of all cases in the general population (White et al., 1994). Deficiency of this enzyme results in an accumulation of 11-deoxysteroid precursors, which are shunted into the androgen pathway. Excess adrenal androgen secretion results in ambiguous genitalia in the affected female fetus. Hypertension in patients with this disorder is commonly attributed to deoxycorticosterone (DOC)-induced sodium retention (Nimkarn and New, 2008b). The hallmark serum abnormality in patients with 11 β -OHD is normal or suppressed renin, because hypokalemia is not uniformly present in all cases. Infants may also present with hyponatremia due to the physiologic newborn resistance to mineralocorticoids. 17-OHP may also be elevated due to the high 11-deoxycortisol levels and be detected by the newborn screen for 21-OHD CAH. Diagnosis is made by the determination of extremely high basal and stimulated levels of DOC and 11-deoxycortisol after performing an ACTH stimulation test. The diagnosis can be confirmed by molecular genetic analysis of the *CYP11B1* gene.

Clinical Signs and Symptoms. Hypertension occurs in approximately two-thirds of patients with 11 β -OHD and distinguishes 11 β -OHD from the more common 21-OHD in cases of virilizing CAH (Rosler et al., 1982; Nimkarn and New, 2008b). However, hypertension correlates variably with the presence of hypokalemia or with the extent of virilization (Rosler et al., 1982). Patients can present with or without hypokalemic alkalosis. It is usually not

identified until later in childhood or in adolescence, although its appearance in early childhood has been documented. A patient was positively identified by the newborn screening program aiming for 21-OHD CAH (Peter et al., 2008).

Epidemiology. Classic 11 β -OHD CAH occurs in approximately 1 in 100,000 births in the general white population (Zachmann et al., 1983). A large number of cases have been reported in Israel, where the incidence was estimated to be 1 in 5000 to 1 in 7000 births, with a gene frequency of 1 in 71 to 1 in 83. A subsequent study showed that 11 β -OHD CAH occurred in a lower frequency (Paperna et al., 2005) yet remains more common in this population than in others. This unexpected clustering of cases was traced to Jewish families of North African origin, particularly from Morocco and Tunisia (Rosler et al., 1992).

Molecular Genetics. Two 11 β -hydroxylase genes have been identified within the human adrenal cortex, each encoding for a different enzyme with distinct enzymatic ability. The two genes *CYP11B1* and *CYP11B2* are located 30 to 40 kilobases apart on chromosome 8q (Chua et al., 1987; Taymans et al., 1998). Although gene conversions occur between *CYP11B1* and *CYP11B2* (Merke et al., 1998; Mulatero et al., 1998), the majority of the mutations found in *CYP11B1* are random point mutations (Rosler et al., 1982; Zachmann et al., 1983; White et al., 1991; Curnow et al., 1993), unlike as found in 21-OHD CAH. By 2003, approximately 41 mutations in *CYP11B1* from individuals of diverse ethnic backgrounds had been identified (Stenson et al., 2003).

Management Issues. Similar to 21-OHD CAH, glucocorticoid therapy is the most effective means of regaining hormonal control in patients with 11 β -OHD. Corticosteroids at the same dose range as for 21-OHD CAH provide feedback inhibition of ACTH, reduce stimulation of the androgen pathway, and allow normal growth and the onset of puberty. Treatment with corticosteroids also contributes to the reduction of DOC and thus controls hypertension. Through careful clinical monitoring, doses can be continuously adjusted to match patients' needs while avoiding suppression of linear growth caused by overdosing. In addition to hormonal therapy, reduced salt intake is often used to reduce fluid volume and hypertension. Maintaining fluid balance in children, however, is often difficult and poses an ongoing challenge to treatment. Affected females suffer from genital ambiguity and may require genital reconstructive surgery after multidisciplinary consultations. To prevent prenatal virilization, a similar protocol to 21-OHD CAH for prenatal diagnosis and treatment can be performed (Cerame et al., 1999).

Disorders That Lead to Males With Undervirilization

17 α -Hydroxylase/17,20-Lyase Deficiency

Pathophysiology. This form of CAH involves an enzyme that catalyzes more than one reaction—namely both the 17 α -hydroxylation and 17,20-lyase reactions—with both reactions commonly being impaired in the disorder. Affected individuals cannot produce cortisol but synthesize large amounts of corticosterone (a weak glucocorticoid that mitigates the adrenal insufficiency) and deoxycorticosterone, which causes hypertension and hypokalemia. Deficiency of 17,20-lyase impairs the ability to synthesize androgens and estrogens and causes male 46,XY disorder of sex development (DSD) at birth and results in failure to virilize at puberty. Affected females have primary amenorrhea and clinical hypogonadism (Yanase et al., 1991; Auchus, 2001).

Clinical Features. The typical features of complete deficiency include hypertension and hypokalemia with delayed puberty in genetic females and undervirilization in genetic males. Nevertheless,

there is considerable variability in the clinical and biochemical features, including a few mutations that cause isolated 17,20-lyase deficiency (Auchus, 2001). The age of onset of hypertension and the severity of hypokalemia are highly variable, even among individuals with the same mutations (Costa-Santos et al., 2004) and occur due to increased ACTH stimulation of the mineralocorticoid pathway.

Epidemiology. This disorder has an estimated frequency in most countries of approximately 1 case per 50,000 newborns and accounts worldwide for approximately 1% of all cases of CAH (Yanase et al., 1991). However, 17-hydroxylase (CYP17) deficiency is the second most common cause of CAH in Brazil (Santos et al., 1998; Costa-Santos et al., 2004), and this remarkable frequency is the result of two founder effects in areas with high coefficients of consanguinity such that two mutations account for more than 80% of cases in that country (Costa-Santos et al., 2004).

Molecular Genetics. Since the cloning of the gene (Picado-Leonard and Miller, 1987) nearly 50 different mutations have been described in *CYP17* (Krawczak and Cooper, 1997). Founder effects probably explain the high incidence of the disease in other patient populations in the Netherlands and Japan (Costa-Santos et al., 2004). Severity of disease tends to be milder with mutations that retain partial catalytic activity, but the nature of the variability in hypertension and hypokalemia is unclear.

Management Issues. Adequate glucocorticoid administration suppresses ACTH and the excessive mineralocorticoid secretion and generally normalizes the blood pressure. Adult females and males reared as females require estrogen therapy. Abdominal testes should be relocated or removed because of the risk of malignancy. Adult genetic males reared as males need surgical correction of the external genitalia and androgen replacement.

3 β -Hydroxysteroid Dehydrogenase Type 2 Deficiency

Pathophysiology. 3 β -Hydroxysteroid dehydrogenase converts 3 β -hydroxy $^5\Delta$ steroids (pregnenolone, 17-hydroxypregnenolone, and DHEA) to 3-keto $^4\Delta$ steroids (progesterone, 17-OHP, and androstenedione) and is essential for the biosynthesis of mineralocorticoids, glucocorticoids, and sex steroids (Mebarki et al., 1995). Two forms of the enzyme have been described in humans: type 1 enzyme expressed in placenta and skin and type 2 expressed in adrenal glands and gonads. The type 1 and 2 genes are closely linked on chromosomal region 1p13.1. The two forms are closely related in structure and substrate specificity, although the type 1 isoenzyme has higher substrate affinity and a fivefold greater enzymatic activity than type 2 (Simard et al., 2005). The type 1 isoenzyme can lead to elevated 17-OHP and androstenedione levels in addition to the expected elevated levels of pregnenolone, 17-hydroxypregnenolone, and DHEA.

Clinical Signs and Symptoms. 3 β -HSD2 isoenzyme is essential for the formation of progesterone, the precursor for aldosterone, 17-OHP, the precursor for cortisol in the adrenal cortex, androstenedione, testosterone, and estrogen. Simultaneous 3 β -HSD2 deficiency in both gonads and adrenal glands results in incomplete virilization of the external genitalia in males. Male patients with 3 β -HSD2 deficiency present with ambiguous external genitalia, characterized by micropenis, perineal hypospadias, bifid scrotum, and blind vaginal pouch (Simard et al., 1994) with or without salt loss (Mebarki et al., 1995). Gynecomastia is common at pubertal stage in affected males. In females, virilization of external genitalia occurs as a result of the androgen effect from the peripheral conversion of circulating $^5\Delta$ precursors to active $^4\Delta$ steroids; therefore genital ambiguity can result in both sexes. Newborns can present

with adrenal insufficiency due to deficiency of glucocorticoids, mineralocorticoids, and sex steroids. Later clinical presentations also include salt-wasting crisis, premature pubic hair development, hirsutism, and menstrual disorders (Lutfallah et al., 2002).

Epidemiology. The exact frequency of this rare disorder remains unknown.

Molecular Genetics. The disorder has an autosomal recessive inheritance. *HSD3B2* is the gene responsible for 3 β -HSD2 deficiency CAH. There are approximately 40 mutations in the *HSD3B2* gene already described (Stenson et al., 2003). Mutations that lead to the abolition of 3 β -HSD2 activity lead to the salt-wasting form (Rheume et al., 1992; Chang et al., 1993; Alos et al., 2000; Lutfallah et al., 2002). Mutations that reduce but do not abolish type II activity lead to CAH with mild or no salt loss, which in males is associated with 46,XY DSD as a result of the reduction in androgen synthesis (Lutfallah et al., 2002). Mild mutations were also associated with hyperandrogenic symptoms of premature pubic hair development and hirsutism (Pang et al., 2002; Mermejo et al., 2005).

Management Issues. Similar to other forms of CAH, corticosteroid is the mainstay therapy. Salt-wasting phenotypes in some patients can be managed the same way as the salt-wasting form of 21-OHD CAH. Male patients with 3 β -HSD2 deficiency have ambiguous external genitalia. Although most males are raised as males and retain the male social sex at puberty, gender identity is an important management issue. In one Brazilian family, two cousins with 46,XY DSD caused by 3 β -HSD2 deficiency were reared as females; one of them had bilateral orchiectomy in childhood and retained the female social sex; the other retained their testes during childhood and changed to male social sex at puberty (Mendonca et al., 1987).

Male patients may require testosterone replacement therapy during puberty and adulthood. The aim of the surgical treatment after consultation with a DSD team in this condition is to allow development of adequate external genitalia. Only skilled surgeons with specific training in the surgery of DSD should perform these procedures (Hughes et al., 2006).

Lipoid Congenital Adrenal Hyperplasia

Lipoid CAH is a severe form of congenital adrenal insufficiency. Affected patients exhibit glucocorticoid and mineralocorticoid deficiencies early in life, and males exhibit undervirilization. The reduced synthesis of steroids in patients with lipoid CAH results from an inability to transfer cholesterol to the inner mitochondrial membrane where the cholesterol side-chain cleavage complex is located (Lin et al., 1995). It is characterized by lipid droplet accumulation in the cytoplasm of the adrenocortical cells. Most cases of lipoid CAH are caused by autosomal recessive mutations in the gene encoding steroidogenic acute regulatory protein (StAR). The *STAR* locus is in the 8p11.2 region and encodes a protein with an essential role in cholesterol transfer from the outer to the inner mitochondrial membrane, thus providing the substrate for steroid hormone biosynthesis (Bose et al., 1996). Once in the mitochondria, cholesterol is converted to pregnenolone by the cytochrome P450 side-chain cleavage (CYP11A1) enzyme, and then steroid biosynthesis is initiated. Karyotypic 46,XY persons are phenotypically female because of Leydig cell destruction and impaired testosterone production. Sertoli cell function though is intact so that anti-müllerian hormone is secreted and thus müllerian ducts regress leading to absence of uterus and fallopian tubes. The ovary in XX subjects is initially spared damage because steroidogenesis is delayed until the time of puberty, after which

stimulation of steroidogenesis by the tropic hormones (i.e., luteinizing and follicle-stimulating hormones) causes progressive damage to the ovary (Fujieda et al., 1997). *StAR* mutations have been described most frequently in Japanese and Palestinian populations, in part because certain mutations occur repeatedly, probably reflecting a founder effect (Bose et al., 1996; Nakae et al., 1997). Although less common than mutations in *StAR*, mutations in *CYP11A1* can also cause lipid CAH (Katsumata et al., 2002; Hiort et al., 2005).

Rare Form of Congenital Adrenal Hyperplasia With Variable Phenotypes

Cytochrome P450 oxidoreductase (POR) deficiency is an autosomal recessive disorder of steroidogenesis involving P450c17, P450c21, and P450-aro with a phenotypic spectrum ranging from cortisol deficiency at the milder end to classic Antley–Bixler syndrome (ABS) at the severe end, and the phenotype of cortisol deficiency can range from clinically insignificant to life threatening (Fluck et al., 2004). Manifestations can include ambiguous genitalia in males and females, primary amenorrhea and enlarged cystic ovaries in females, poor masculinization during puberty in males, and maternal virilization and low estriol levels during pregnancy with an affected fetus carrying certain POR mutations. Manifestations of ABS include craniosynostosis, hydrocephalus, distinctive facies, choanal stenosis or atresia, low-set, dysplastic ears with stenotic external auditory canals, skeletal anomalies (radiohumeral synostosis, neonatal fractures, congenital bowing of the long bones, joint contractures, arachnodactyly, clubfeet), renal anomalies (ectopic kidneys, duplication of kidneys, renal hypoplasia, horseshoe kidney, hydronephrosis), and reduction of cognitive function and developmental delay. The skeletal differences have been hypothesized to be due to decreased activity of CYP26B1, a POR-dependent enzyme that degrades retinoic acid (Laue et al., 2011). In moderate POR deficiency, craniofacial and skeletal anomalies are less severe than in ABS (Scott and Miller, 2008). Infants with ABS with normal steroidogenesis and without ambiguous genitalia have a mutation in the fibroblast growth factor receptor 2 and not in the *POR* gene (Huang et al., 2005). As more and more patients are identified with POR deficiency, this newly discovered form of CAH may not be as rare as formerly thought.

Familial Glucocorticoid Deficiency

Familial glucocorticoid deficiency (FGD) is an autosomal recessive disorder resulting from defects in the action of ACTH to stimulate glucocorticoid synthesis in the adrenal leading to ACTH resistance. It is also known as isolated glucocorticoid deficiency or hereditary unresponsiveness to ACTH. The majority of patients with FGD have episodes of hypoglycemia in the neonatal period. These episodes will often respond quickly to more frequent feeding regimens. In a few cases, excessive skin pigmentation is recognized at this early stage. Biochemically, patients with FGD have low or undetectable cortisol levels and—because of the failure of the negative feedback loop to the pituitary and hypothalamus—grossly elevated ACTH levels are found. Mineralocorticoid deficiency usually is not a presentation; therefore aldosterone levels, plasma renin measurements, and serum electrolytes are normal. A clinical feature sometimes observed in patients with FGD is tall stature that is identified later in life (Elias et al., 2000). Approximately half of all cases result from mutations in the ACTH receptor (*MC2R*, melanocortin 2 receptor) FGD type

1 or from mutations in the melanocortin 2 receptor accessory protein (*MRAP*), FGD type 2, but other genetic causes of this potentially lethal disorder remain to be discovered (Clark et al., 2009).

Triple A Syndrome

Triple A or Allgrove syndrome is a similar disorder to FGD, with additional features of alacrima and achalasia. Alacrima is the first symptom, followed by achalasia and then adrenal insufficiency. Presenting in the first decade of life, it is frequently associated with progressive neurologic dysfunction, polyneuropathy, deafness, mental retardation, and hyperkeratosis of palms and soles (Houlden et al., 2002). Some of these families have a defect in the alacrima–achalasia–adrenal insufficiency neurologic disorder (*AAAS*) gene encoding a protein named ALADIN (Tullio-Pelet et al., 2000). ALADIN participates in the nuclear translocation of the ferritin heavy chain protein. Mutations in *AAAS* prevent ferritin heavy chain protein from entering into the nucleus, which is necessary to prevent oxidative damage of the nucleus (Storr et al., 2009). ALADIN belongs to a WD-repeat family of regulatory proteins that shares a common motif made up of highly conserved repeating units usually ending with tryptophan-aspartate (WD) (Neer et al., 1994).

Neonatal Adrenoleukodystrophy

Neonatal adrenoleukodystrophy (NALD) is a fatal rare autosomal recessive disease of impaired peroxisome biogenesis. NALD belongs to a class of disorders involving peroxisomal biogenesis that includes Zellweger syndrome and infantile Refsum disease. NALD is the only one of the three diseases that often involves adrenal insufficiency. Mutations in seven different peroxisome biogenesis factor genes have been shown to cause NALD (Moser, 1999). Mutations in peroxisome biogenesis factor 1 (*PEX1*) are the most common cause of NALD (Tamura et al., 2001). As in X-linked adrenoleukodystrophy (X-ALD), patients with NALD accumulate very long chain fatty acids and develop degenerative changes of the white matter of the nervous system and adrenal atrophy. Infants with NALD characteristically demonstrate dolichocephaly, prominent and high forehead, esotropia, epicanthic folds, broad nasal bridge, high-arched palate, low-set ears, and anteverted nostrils. Affected patients usually die in early childhood (Walter et al., 2001). X-ALD is a recessively inherited X-linked defect of the adrenoleukodystrophy protein (ALDP) (Lightenberg et al., 1995). It is encoded by the *ABCD1* gene on Xq28. It is also a peroxisomal defect that usually results in adrenal insufficiency and central nervous system deterioration. X-ALD can present in early childhood, and at birth there is already elevation of very long chain fatty acids. Because early diagnosis can improve outcome through the use of hematopoietic stem cell transplantation or gene therapy (research), some state newborn screening programs have added X-ALD to their newborn screening panel. X-ALD can also manifest later in adulthood (Moser et al., 1984).

Defective Cholesterol Metabolism: Smith–Lemli–Opitz Syndrome

The clinical picture of adrenal insufficiency and 46,XY gonadal dysgenesis may be caused by a deficiency of 7-dehydrocholesterol C-7 reductase enzyme that catalyzes the final step in cholesterol biosynthesis leading to primary adrenal insufficiency. The syndrome

results from mutations in the sterol Δ -7-reductase gene (*DHCR7*) located at 11q12-q13. Smith–Lemli–Opitz (SLO) syndrome can manifest with typical facial appearance, mental retardation, microcephaly, proximally placed thumbs, congenital cardiac abnormalities, syndactyly of the second and third toes, incomplete development of the male genitalia, and photosensitivity. The biochemical abnormalities of SLO syndrome include low cholesterol and high 7-dehydrocholesterol (Tint et al., 1994). In utero, the primary defect in fetal adrenal glands results in a combination of low maternal estriol levels, undervirilization of the male fetus, and large adrenal glands in the fetus with SLO syndrome. Preliminary studies suggested that cholesterol supplementation may be of benefit to patients with SLO syndrome (Andersson et al., 1999). Unfortunately replacement of cholesterol has not been as beneficial as once hoped. Cholesterol does not cross the blood–brain barrier and has not been shown to reduce developmental delay (Sikora et al., 2004). A more recent placebo-controlled trial using simvastatin found that the medication crossed the blood–brain barrier and was relatively safe. There was improvement in serum dehydrocholesterol-to-total sterol ratio and improvement of irritability symptoms (Wassif et al., 2017). The birth prevalence of SLO syndrome is estimated to be approximately 1:20,000 to 1:40,000 live births (Tint et al., 1994). Among persons of northern or central European ancestry, it has been estimated to range from 1:10,000 to 1:60,000 (Porter, 2000). SLO syndrome is less common in those of Asian or African ancestry. As it is an autosomal recessive disorder, the recurrence risk is 25%. Thus it is important to consider the diagnosis as an elevated 7-dehydroxycholesterol level will confirm the diagnosis.

Adrenal Insufficiency Associated With Other Syndromic Disorders

Lysosomal Storage Disorders

Complete deficiency of lysosomal esterase can also result in adrenal insufficiency in Wolman disease, a rare autosomal recessive disease with an incidence of 1 in 350,000 infants. Wolman disease usually is fatal in the 1st year of life. Affected infants exhibit mild mental retardation, hepatosplenomegaly, vomiting, diarrhea, growth failure, and adrenal calcifications. Calcifications that delineate the outline of both adrenals are pathognomonic of this condition (Wolman, 1995).

Mitochondrial Disorders

Adrenal insufficiency can result from mitochondrial disorders, characterized by chronic lactic acidosis, myopathy, cataracts, and nerve deafness (Nicolino et al., 1997; Bruno et al., 1998). Cases with the Kearns–Sayre syndrome form of mitochondrial myopathy and deafness, with large-scale deletions in mitochondrial DNA, are often associated with endocrine dysfunction, particularly short stature, hypogonadism, diabetes, hypoparathyroidism, hypothyroidism, and adrenal insufficiency (Artuch et al., 1998; Boles et al., 1998).

Intrauterine Growth Retardation, Metaphyseal Dysplasia, Adrenal Hypoplasia Congenita, and Genital Anomalies

Three patients with AHC and additional findings that represent a new syndrome known as *IMAGe* (i.e., intrauterine growth retardation, metaphyseal dysplasia, AHC, and genital anomalies) have been reported. Genital abnormality was described as bilateral cryptorchidism, small penis, and hypogonadotropic hypogonadism.

The patients also had hypercalciuria with or without hypercalcemia resulting in abnormal calcium deposits in vital organs (Vilain et al., 1999). As of 2016, 28 individuals in 16 families have been reported (Bennett et al., 2016). Mutations in the proliferating cell nuclear antigen (PCNA) binding domain of the maternally expressed cyclin-dependent kinase inhibitor (*CDKN1C*) gene on the short arm of chromosome 11, which results in the loss of PCNA binding, have been identified as the etiology of *IMAGe* syndrome. These mutations serve as a gain of function mutation (Arboleda et al., 2012). *CDKN1C* is a tumor suppressor gene, and it encodes an inhibitor of cell cycle progression. Beckwith–Wiedemann syndrome, an overgrowth syndrome, also has mutations in the *CDKN1C* gene but at a different location, resulting in a loss of function.

Adrenal Hypoplasia Congenita

AHC, a familial condition in which the adrenal cortex has arrested development, occurs in approximately 1 in 12,500 births (Laverty et al., 1973; Jones et al., 1995). The disorder can manifest as four clinical forms of primary adrenal insufficiency: (1) a sporadic form associated with pituitary hypoplasia; (2) an autosomal recessive form with a distinct miniature adult adrenal morphology, characterized by small glands with a permanent cortical zone but a diminished fetal zone (the genetic basis of the recessive form of AHC is unknown); (3) an X-linked cytomegalic form associated with hypogonadotropic hypogonadism; and (4) an X-linked form associated with glycerol kinase deficiency and Duchenne muscular dystrophy (Bartley et al., 1982; Ten et al., 2001). Mutations in the *NROB1* gene encoding DAX-1 are responsible for both X-linked forms.

The X-linked or cytomegalic form of AHC is characterized by the absence or near absence of the permanent or adult zone of the adrenal cortex and by structural disorganization of the fetal cortex with abnormally large cells. It differs from the autosomal recessive miniature adult form of AHC, in which the adrenal cortex has the normal adult structure but is small. X-linked AHC results in severe primary adrenal insufficiency involving glucocorticoids and mineralocorticoids and failure to respond to elevated levels of ACTH with usual age at onset in the neonatal period or during infancy. However, in some patients, age of onset is later, up to several years of age and presumably caused by residual functional cortex (McCabe, 2000; Achermann et al., 2001). The secretion of other pituitary hormones is not impaired. Hypogonadotropic hypogonadism can manifest with cryptorchidism or delayed puberty (Golden et al., 1977). Whereas presentation of adrenal insufficiency can occur from birth, there is great variability of presentations. Isolated adrenal insufficiency in infancy, isolated adrenal insufficiency later in life, isolated hypogonadotropic hypogonadism, adrenal insufficiency and hypogonadotropic hypogonadism, delayed-onset adrenal insufficiency from 2 to 9 years of age with incomplete hypogonadotropic hypogonadism, and delayed puberty in females all may result (Ten et al., 2001). The phenotypic variation does not correlate well with genotype.

Adrenal Hypoplasia as Part of Contiguous Gene Deletion Syndrome

An X-linked form of adrenal insufficiency, associated with glycerol kinase deficiency, is characterized by psychomotor retardation, muscular dystrophy, characteristic facies with hypertelorism, alternating strabismus, and drooping mouth. Additional phenotypic features can include testicular abnormalities (anorchia or cryptorchidism), short stature, and osteoporosis. Time of presentation

can vary from birth through childhood. Nearly all patients reported were male. The genetic locus was mapped to Xp21.3-21.2, and variants of contiguous gene deletion syndrome (glycerol kinase deficiency, Duchenne muscular dystrophy, ornithine transcarbamylase deficiency, and mental retardation) can be seen.

Abnormalities of Development: DAX-1 and Steroidogenic Factor-1 Deficiency

The nuclear receptors DAX-1 and SF-1 (Phelan and McCabe, 2001) have an important role in adrenal development and function, and mutations in the genes that encode these transcription factors have been found in patients with adrenal hypoplasia (see Molecular Basis of Adrenal Development, earlier). Both SF-1 and DAX-1 belong to the family of nuclear hormone receptors. DAX-1 protein is expressed in the developing urogenital ridge, ovary, testis, all zones of the fetal adrenal cortex, hypothalamus, and anterior pituitary gland—sites in which it colocalizes with SF-1 (Guo et al., 1995; Parker et al., 2002). SF-1 is essential for the development of the adrenal cortex, gonads, and ventromedial nucleus of the hypothalamus because it interacts with the promoter of the *NROB1* gene, anti-müllerian hormone gene, and the genes for the α -subunits of the pituitary glycoprotein hormones (Kawabe et al., 1999). Furthermore, SF-1 is a transcription factor that regulates gene expression of the CYP steroid hydroxylases (21-hydroxylase, the aldosterone synthase isoenzyme of steroid 11 β -hydroxylase, CYP11A), 3 β -hydroxysteroid dehydrogenase, aromatase, and StAR in the adrenal gland; therefore it is essential for development of the adrenal cortex.

In one large study of this relatively rare disease, *NROB1* mutations were found in 58% of 46,XY phenotypic boys referred with adrenal hypoplasia and in all boys with hypogonadotropic hypogonadism and a family history suggestive of adrenal failure in males. *NR5A1* (SF-1) mutations causing adrenal failure were found in only two patients with 46,XY gonadal dysgenesis. No *NROB1* or *NR5A1* mutations were identified in the adult-onset group (Lin et al., 2006).

Human mutations in *NR5A1* are even less common and have been described in a few patients with primary adrenal failure. Two individuals with a 46,XY genotype, female phenotype, and müllerian structures harbored missense mutations that affected DNA binding (Achermann et al., 1999, 2002), whereas a 46,XX girl with an *NR5A1* mutation had primary adrenal failure and apparently normal ovarian development (Biaison-Laubert and Schoenle, 2000). In addition, it is now emerging that heterozygous nonsense or frameshift mutations associated with haploinsufficiency of *NR5A1* can cause 46,XY gonadal dysgenesis in patients with normal adrenal function (Correa et al., 2004; Hasegawa et al., 2004; Mallet et al., 2004). Therefore it is possible that a range of different endocrine phenotypes are associated with mutations in different domains of *NR5A1*.

Adrenal Hemorrhage

Adrenal hemorrhage is not uncommon at birth. At birth, adrenal hemorrhage from anoxia or sepsis is most common, and adrenal insufficiency usually manifests in neonates. The incidence in the neonate is reported to be 1.7 cases per 1000 autopsied infants and as many as 3% of infants screened by abdominal ultrasound examination. The etiology of neonatal adrenal hemorrhage is largely unknown, but it has been associated with birth trauma related to difficult deliveries, sepsis, coagulopathies, traumatic shock, and ischemic disorders. Infants with minimal hemorrhage may be asymptomatic and be discovered incidentally to have adrenal

calcifications, indicating an earlier hemorrhage. Major adrenal hemorrhage can manifest as an abdominal mass, anemia from blood loss, or jaundice from reabsorption of the hematoma. Hemorrhage can also lead to adrenal insufficiency, which can manifest as neonatal hypoglycemia, hypotension, hypothermia, apnea, or shock. Because of the location of the right adrenal gland between the liver and spine, it is the one most often affected by hemorrhage (Velaphi and Perlman, 2001).

In meningococcal septicemias, hemorrhage into the adrenal glands can complicate the clinical picture, leading to circulatory collapse (Waterhouse–Friderichsen syndrome or adrenal hemorrhage in association with fulminant septicemia; Enriquez et al., 1990). Other infections in the neonate that have been associated with adrenal hemorrhage and insufficiency include those caused by herpes virus, *Pseudomonas aeruginosa*, *Bacteroides* spp., herpes simplex virus type 6, and echovirus types 11 and 6 (Margaretten et al., 1963; Ohta et al., 1978; Bekdash and Slim, 1981; Jain et al., 1996; Schmitt et al., 1996). Septic shock in newborns, especially in those who are small for their age, can result in adrenal hemorrhage with rhabdomyolysis and renal insufficiency (Ten et al., 2001).

Secondary and Tertiary Adrenal Insufficiency

Iatrogenic Adrenal Insufficiency

Secondary and tertiary forms of adrenal insufficiency result from defects in pituitary corticotroph and hypothalamic function, respectively. Supraphysiologic doses of glucocorticoids are often used for the treatment of bronchopulmonary dysplasia. With prolonged use of supraphysiologic doses of glucocorticoids, these neonates are at risk for iatrogenic suppression of corticotroph ACTH release, with secondary adrenocortical atrophy and adrenal insufficiency (Axelrod, 1992). Evidently, even a single course of prenatal betamethasone treatment induces a suppression of stress reactivity in healthy newborns (Schaffer et al., 2009). The duration of recovery of corticotroph function from adrenal suppression, once administration of glucocorticoids is discontinued, is highly variable with evidence of suppression of the HPA axis evident in some patients for more than 1 year (Livanou et al., 1967). Even in preterm infants, the HPA axis behaves in a similar manner as in adult subjects, and the pituitary function recovers earlier than that of the hypothalamus and the adrenals (Ng et al., 2008).

Developmental Adrenal Insufficiency

Secondary or tertiary adrenal insufficiency in the neonate often is a consequence of abnormalities in development of the hypothalamus and pituitary associated with adrenal insufficiency, including de Morsier syndrome (septo-optic dysplasia; De Morsier, 1956), hydranencephaly or anencephaly, and pituitary hypoplasia or aplasia. If these infants have concomitant diabetes insipidus, they have an increased risk of sudden death during childhood (Dattani et al., 1998; Kelberman et al., 2006). Patients with developmental abnormalities of the pituitary or hypothalamus often have deficiencies of other hormones. ACTH deficiency can be part of a multiple pituitary hormone deficiency syndrome caused by abnormal expression of *HESX1*, *LHX4*, *SOX3*, or *PROPI*, which encode transcription factors (Mullis, 2001). Isolated ACTH insufficiency is a rare condition that can be caused by mutations in *TPIT*, a T-box factor that controls transcription of the proopiomelanocortin gene in corticotrophs only, thereby resulting in an adrenal-only phenotype (Vallette-Kasic et al., 2005). However, approximately

50% of patients do not carry mutations in *TPIT*, suggesting that other unknown factors exist (Metherell et al., 2004; Vallette-Kasic et al., 2004). Septo-optic dysplasia can be caused by mutations in *HESX1* and *SOX2* (Dattani et al., 1998; Kelberman et al., 2006). Signs of hypopituitarism in a neonate include hypoglycemia, prolonged jaundice, shock, and microphallus in males. Trauma to the hypothalamus, pituitary, or hypophyseal portal circulation from significant head injury, cerebrovascular accident, Sheehan syndrome, or hydrocephalus may be a cause of central adrenal insufficiency. Historical factors associated with increased risk for central adrenal insufficiency include maternal drug use and traumatic delivery.

There have been rare case reports of families with inherited abnormalities of neuropeptides involved in HPA axis regulation. Adrenal insufficiency, pigmentary abnormalities, and obesity have been described in families with a defect in proopiomelanocortin (POMC) (Krude et al., 1998). One kindred has been reported with Arnold–Chiari type I malformation and suspected *CRH* deficiency. The mutation in this kindred is linked to the *CRH* locus; however, a specific mutation in the *CRH* gene has not yet been defined (Kyllo et al., 1996). Mutations in *TPIT*, which encodes a highly restricted transcription factor involved in the expression of the *POMC* gene, have been found in eight individuals with congenital isolated ACTH deficiency. It is an autosomal recessive disorder (Pulichino et al., 2003).

Management

Adrenal crisis is a potentially life-threatening disorder that can manifest with a salt-losing crisis or profound hypoglycemia in infancy or childhood and requires immediate resuscitation and appropriate steroid replacement. Determining the exact cause of this condition can be challenging once the child has started treatment, but defining a precise etiology has important implications for long-term management, for identifying associated features, and for appropriate counseling regarding inheritance and the risks of other family members being affected (Lin et al., 2006). Detailed questioning about family history that could reveal any insight into possible adrenal disease is important.

Initial Management

In the event of a suspected adrenal crisis, blood for determination of electrolytes, aldosterone, plasma renin activity, cortisol, and ACTH should be drawn and treatment started before the results are obtained. Fluid resuscitation with normal saline containing 5% or 10% dextrose should be given to restore cardiovascular stability. Plasma sodium should be monitored closely, as rapid correction of hyponatremia with sodium repletion of more than 0.5 to 1 milliequivalent (mEq)/L per hour increases the risk of central pontine myelinolysis. The sodium deficit may be calculated by subtracting the infant's sodium from a customarily normal sodium of 140 mEq/L and then multiplying this value by $0.6 \times \text{weight (in kg)}$. The rate of replacement should occur over an initial rate such that the sodium increase does not exceed 0.5 mEq/L per hour. Hydrocortisone IV should be given initially at 100 mg/m² and then continued at 100 mg/m² per day, divided every 6 to 8 hours, until the infant's condition is stable.

Maintenance Therapy

Corticosteroid and mineralocorticoid replacement therapies should suppress the excessive secretion of CRH, ACTH, and resting renin

levels. The normal daily cortisol production rate has been shown to be 6 to 7 mg/m² per day in children and adolescents (Linder et al., 1990; Kerrigan et al., 1993). This rate translates to approximately 10 to 12 mg/m² per day of oral hydrocortisone, to allow for step-down losses from absorption, hepatic processing, and metabolic bioavailability. Because the bioavailability of oral steroids varies from person to person (Bright and Darmaun, 1995), infants should be monitored closely for signs of either inadequate cortisol replacement or cortisol excess (Heazelwood et al., 1984). Although adults and older children may be able to take hydrocortisone twice daily, most infants should be dosed three times daily to avoid hypoglycemia associated with low cortisol on a twice-daily regimen (Groves et al., 1988; DeVile and Stanhope, 1997). Hydrocortisone is the preferred steroid for treatment of infants because it has fewer growth-suppressive effects than synthetic steroids (Allen, 1996; Allen et al., 1998; Punthakee et al., 2003). The United States Food and Drug Administration withdrew oral hydrocortisone suspension from the market because of poor absorption and undertreatment of children (Ten et al., 2001). The smallest tablet for hydrocortisone is 5 mg, and it can be cut into quarters for a dose of 1.25 mg.

In primary adrenal insufficiency, aldosterone production is usually decreased. Physiologic doses of hydrocortisone do not provide enough mineralocorticoid activity to prevent salt wasting (New et al., 1966); therefore these infants often require 0.05 to 0.4 mg/day of fludrocortisone acetate (Florinef, 9 α -fluorocortisol) and added salt. Because after the 1st month of life aldosterone production does not vary, the dose of fludrocortisone does not increase with growth and aging (Weldon et al., 1967; Sippell et al., 1978). Infants with mineralocorticoid deficiency require 1 to 2 g of sodium chloride (1 g contains 17 mEq of sodium) added to their diet, because formula and breast milk are low in sodium content (approximately 8 mEq/L) (Mullis et al., 1990).

Stress Replacement

The normal response to surgery, trauma, or critical illness is to increase plasma ACTH and cortisol levels (Lamberts et al., 1997). The secretion rate of cortisol has been found to be proportional to the degree of stress and ranges from 60 to 167 mg/day in adults after surgery (Hume et al., 1962; Chernow et al., 1987). Based on data from adults, it is recommended that infants with adrenal insufficiency receive 30 to 100 mg/m² per day of hydrocortisone when stressed, divided every 6 to 8 hours. Stress doses of hydrocortisone should be given with the onset of fever and gastrointestinal or other significant illness and continued for 24 hours after the symptoms resolve (Nimkarn and New, 2008a). Usually this treatment translates to the routine steroid dose being tripled and administered over three divided daily doses. If oral steroids are not tolerated, an intramuscular or IV dose should be given. For surgery, infants should be given 30 to 100 mg/m² of IV hydrocortisone on call to the operating room before the administration of anesthesia. Alternatively the 30 to 100 mg/m² of hydrocortisone can be given continuously during the surgery in the IV fluids. Stress dosing of hydrocortisone (30 to 100 mg/m² per day divided every 6 to 8 hours) should be continued postoperatively for the next 24 to 48 hours. It is unnecessary to give mineralocorticoids over such periods if the patient begins the operative period in adequate salt balance.
